CYCLOPÆDIA

OF THE

DISEASES OF CHILDREN

MEDICAL AND SURGICAL.

THE ARTICLES WRITTEN ESPECIALLY FOR THE WORK BY
AMERICAN, BRITISH, AND CANADIAN AUTHORS.

EDITED BY
JOHN M. KEATING, M.D.

VOL. III.

ILLUSTRATED.

PHILADELPHIA:
J. B. LIPPINCOTT COMPANY.
1891.

CONTENTS OF VOLUME III.

PART I.

DISEASES OF THE DIGESTIVE SYSTEM.

PAGE

FUNCTIONAL DISORDERS OF THE STOMACH. By William Pepper, M.D., LL.D., Philadelphia, Pa., Provost and Professor of Theory and Practice of Medicine in the University of Pennsylvania 1

DISEASES OF THE STOMACH. By Hobart Amory Hare, M.D., Philadelphia, Pa., Clinical Professor of Diseases of Children in the University of Pennsylvania; Physician to the Children's Dispensary of the University Hospital. 30

THE DIARRHŒAL DISEASES, ACUTE AND CHRONIC. By L. Emmett Holt, M.D., Professor of the Diseases of Children in the New York Polyclinic; Attending Physician to the New York Infant Asylum and to the Babies' Hospital; Consulting Physician to the Hospital for the Ruptured and Crippled . 61

MEMBRANOUS ENTERITIS. By Wm. A. Edwards, M.D., San Diego, California, formerly Instructor in Clinical Medicine and Physician to Medical Dispensary in the University of Pennsylvania; Fellow of the College of Physicians of Philadelphia, etc. 163

INTESTINAL BACTERIA OF CHILDREN. By William D. Booker, M.D., Baltimore, Md., Professor of Diseases of Children in the Women's Medical College of Baltimore; Physician-in-charge of the Thomas Wilson Sanitarium for Sick Children, etc. 170

ACUTE AND CHRONIC CONSTIPATION. By Charles Warrington Earle, M.D., Chicago, Ill., Professor of Pediatrics and Clinical Medicine, Women's Medical College; Obstetrician and Gynæcologist, Cook County Hospital, etc. 191

TABES MESENTERICA. By A. Jacobi, M.D., New York, ex-President of New York Academy of Medicine; Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, etc. 208

PARASITES OF THE INTESTINAL CANAL. By W. T. Councilman, M.D., Baltimore, Md., Associate Professor of Anatomy, Johns Hopkins University, etc. 217

HERNIA IN CHILDREN. By William J. Taylor, M.D., Philadelphia, Pa., Surgeon to St. Mary's Hospital; Assistant Surgeon to the Orthopædic Hospital, etc. 231

INTESTINAL OBSTRUCTION IN CHILDREN. By W. W. Keen, M.D., Philadelphia, Pa., Professor of Principles and Practice of Surgery, Jefferson Medical College; Surgeon to St. Mary's Hospital, etc. 247

PAGE

PERITONITIS. By HENRY ASHBY, M.D., M.R.C.P., Manchester, England, Physician to the Hospital for Sick Children, Pendlebury, Manchester; Lecturer on Diseases of Children, Victoria University; Vice-President of the Section of Diseases of Children of the British Medical Association, 1888 268

PERITYPHLITIS, PARATYPHLITIS, PERITYPHLITIC ABSCESS. By CHRISTIAN FENGER, M.D., Chicago, Ill., Professor of Clinical Surgery, College of Physicians and Surgeons, Chicago; Attending Surgeon to the Cook County Hospital and to the German Hospital; Fellow of the German Surgical Association (Germany), etc. 282

CONGENITAL ABNORMALITIES OF THE INTESTINE.—MALFORMATIONS, INJURIES, AND DISEASES OF THE RECTUM AND ANUS. By HENRY R. WHARTON, M.D., Philadelphia, Pa., Surgeon to the Children's Hospital; Instructor in Clinical Surgery and Lecturer on Surgical Diseases of Children, University of Pennsylvania; Assistant Surgeon to the Hospital of the University of Pennsylvania 315

COLOTOMY. By JOHN H. PACKARD, M.D., Philadelphia, Pa., Surgeon to the Pennsylvania and St. Joseph's Hospitals, etc. 357

THE PANCREAS.

DISEASES OF THE PANCREAS, AND THEIR OPERATIVE TREATMENT. By N. SENN, M.D., Milwaukee, Wis., Professor of Surgery, College of Physicians and Surgeons, Chicago; Surgeon to the Milwaukee Hospital, etc. 365

THE LIVER.

FUNCTIONAL DISORDERS OF THE LIVER, JAUNDICE, AND DISEASES OF THE DUCTS AND OF THE PORTAL VEIN. By HENRY DWIGHT CHAPIN, M.D., New York, Professor of Diseases of Children at the New York Post-Graduate Medical School and Hospital and at the Women's Medical College of the New York Infirmary; Attending Physician to the Demilt Dispensary 403

ENLARGEMENTS OF THE LIVER. By J. H. MUSSER, M.D., Philadelphia, Pa., Assistant Professor of Clinical Medicine, University of Pennsylvania; Attending Physician to the Philadelphia and Presbyterian Hospitals, etc. 422

CONTRACTIONS OF THE LIVER. By MARCUS P. HATFIELD, M.D., Chicago, Ill., Professor of Diseases of Children, Chicago Medical College; Physician to the Chicago Orphan Asylum; Member of the Council of Diseases of Children of the International Medical Congress, Washington, D.C., etc. 488

PART II.

DISEASES OF THE GENITO-URINARY ORGANS.

ANOMALIES OF THE KIDNEY: NUMBER, FORM, AND POSITION. By GEORGE B. FOWLER, M.D., New York, Professor of Clinical Medicine and Medical Chemistry, Post-Graduate Medical School and Hospital; Visiting Physician to Bellevue Hospital and the New York Infants' Asylum, etc. 516

ALBUMINURIA IN CHILDREN. By JAMES TYSON, M.D., Professor of Clinical Medicine in the University of Pennsylvania 525

PAGE

ACUTE AND CHRONIC BRIGHT'S DISEASE. By JAMES F. GOODHART, M.D., F.R.C.P., London, England, Physician to Evelina Hospital for Sick Children; Physician and Lecturer on Pathology in Guy's Hospital, etc. 532

SURGICAL DISEASES OF THE KIDNEY. By HENRY MORRIS, M.D., F.R.C.S., London, England, Lecturer on Surgery, Middlesex Hospital, etc. . . . 559

ENURESIS—INCONTINENCE OF URINE. By A. JACOBI, M.D., ex-President of New York Academy of Medicine; Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, etc. 591

VESICAL, URETHRAL, AND PREPUTIAL CALCULI. By WILLIAM HUNT, M.D., Philadelphia, Pa., Senior Surgeon to the Pennsylvania Hospital . 596

MALFORMATIONS OF THE PENIS, URETHRA, AND BLADDER. By DE FOREST WILLARD, M.D., Philadelphia, Pa., Clinical Professor of Orthopædic Surgery, University of Pennsylvania; Surgeon to the Presbyterian Hospital 633

DISEASES OF THE BLADDER. By A. VANDER VEER, M.D., Albany, N.Y., Professor of Didactic, Abdominal, and Clinical Surgery, Albany Medical College; Attending Surgeon to Albany Hospital; Consulting Surgeon to St. Peter's Hospital, etc. 674

DISEASES OF THE UMBILICUS. By WILLIAM LEE, M.D., Baltimore, Md., Professor of Diseases of Children, Hygiene, and Dermatology, Baltimore Medical College, etc. 683

DISEASES OF THE TESTES AND PENIS. By F. R. STURGIS, M.D., New York, Surgeon to the Charity Hospital, Blackwell's Island, etc. 691

DISEASES OF THE UTERUS, VAGINA, AND VULVA. By JOHN M. KEATING, M.D., Philadelphia, Pa., Visiting Obstetrician to the Philadelphia Hospital; Gynæcologist to St. Joseph's Hospital; Consulting Physician for the Diseases of Women, St. Agnes' Hospital; Physician to the Children's Department, Howard Hospital, etc. 711

DISEASES OF THE OVARIES AND TUBES. By HOWARD A. KELLY, M.D., Baltimore, Md., Professor of Gynæcology at Johns Hopkins University, etc. 731

ABNORMALITIES OF FEMALE GENITAL ORGANS AND MAMMARY GLANDS. By CLARA MARSHALL, M.D., Philadelphia, Pa., Professor of Therapeutics in the Women's Medical College, Philadelphia; Visiting Obstetrician to the Philadelphia Hospital, etc. 741

THE BLOOD.

DISEASES OF THE BLOOD AND BLOOD-MAKING APPARATUS. By J. P. CROZER GRIFFITH, M.D., Philadelphia, Pa.; Instructor in Clinical Medicine in the University of Pennsylvania, and Assistant Physician to the Hospital of the same; Physician to St. Agnes' and Howard Hospitals, to the Southern Home for Children, and to the Medical Clinic of the Children's Hospital 755

PART III.

SURGERY.

PAGE

MINOR SURGERY AND EMERGENCIES IN CHILDREN. By Charles W. Dulles, M.D., Philadelphia, Pa., Surgeon to Out-Patients, University Hospital and Presbyterian Hospital, Philadelphia; Member of the Academy of Surgery, Philadelphia, etc. 839

PLASTIC SURGERY. By Thomas G. Morton, M.D., Philadelphia, Pa., Surgeon to the Pennsylvania Hospital, etc. 864

WOUNDS (including Contused, Lacerated, and Poisoned, and Complications, Pyæmia, Septicæmia, Erysipelas, Tetanus, Gangrene, Cellulitis, Lymphangitis, Hydrophobia, Poisoning from Venomous Reptiles and Insects, etc.). By James McCann, M.D., Pittsburg, Pa., Surgeon to the Western Pennsylvania Hospital; Professor of Surgery at the Western Pennsylvania Medical College, etc. 868

ANÆSTHETICS AND ANÆSTHESIA. By Oscar H. Allis, M.D., Philadelphia, Pa., Attending Surgeon to the Presbyterian Hospital 913

PART IV.

DISEASES OF THE OSSEOUS SYSTEM AND OF THE JOINTS.

CONGENITAL ABNORMALITIES OF THE EXTREMITIES. By Thomas R. Neilson, M.D., Philadelphia, Pa., Surgeon to the Episcopal Hospital; Instructor in Genito-Urinary Diseases and Assistant Demonstrator of Anatomy in the University of Pennsylvania, etc. 929

CONGENITAL DISLOCATIONS. By Samuel Ketch, M.D., New York, Visiting Orthopædic Surgeon to Randall's Island Hospitals, Department of Public Charities and Correction, New York City; Senior Assistant Surgeon to New York Orthopædic Dispensary and Hospital, and Le Roy W. Hubbard, M.D., Senior Assistant Surgeon to the New York Orthopædic Dispensary and Hospital, etc. 945

CLUB-FOOT. By E. H. Bradford, M.D., Boston, Mass., Surgeon to the Children's Hospital; Surgeon to the City Hospital; Assistant in Clinical Surgery, Harvard Medical School, etc., and E. G. Brackett, M.D., Assistant Surgeon to the Out-Patient Department, Children's Hospital, etc. 955

TORTICOLLIS. By E. H. Bradford, M.D., Boston, Mass., Surgeon to the Children's Hospital; Surgeon to the City Hospital; Assistant in Clinical Surgery, Harvard Medical School, etc., and E. G. Brackett, M.D., Assistant Surgeon to the Out-Patient Department, Children's Hospital, etc. 979

ACUTE INFLAMMATION OF BONE. By William Macewen, M.D., Glasgow, Scotland, Lecturer on Systematic and Clinical Surgery, Glasgow Royal Infirmary; Surgeon to Royal Infirmary and Children's Hospital 992

PAGE

LATERAL AND FUNCTIONAL CURVATURES OF THE SPINE. By V. P. Gibney, M.D., New York, Professor of Orthopædic Surgery at the New York Polyclinic; Surgeon-in-chief to the Hospital for Ruptured and Crippled, New York, etc. 1001

POTT'S DISEASE. By A. Sydney Roberts, M.D., Philadelphia, Pa., Vice-President of the American Orthopædic Association, etc. 1019

FRACTURES AND DISLOCATIONS. By John H. Packard, M.D., Philadelphia, Pa., Surgeon to the Pennsylvania Hospital and to St. Joseph's Hospital. 1043

SYNOVITIS—ARTHRO-MENINGITIS. By A. J. Steele, M.D., St. Louis, Mo., Professor of Orthopædic Surgery and Joint-Diseases, St. Louis Post-Graduate School of Medicine; Attending Surgeon to Department of Deformities and Diseases of the Joints, Augusta Hospital for Children; Professor of Orthopædic Surgery and Diseases of the Joints, Beaumont Medical College, etc. 1127

DISEASES OF THE MAJOR ARTICULATIONS. By Charles T. Poore, M.D., New York, Surgeon to St. Mary's Hospital for Children, New York, etc. 1139

DISEASES OF THE MINOR ARTICULATIONS. By D. A. K. Steele, M.D., Chicago, Ill., Professor of the Principles and Practice of Surgery and Clinical Surgery, College of Physicians and Surgeons of Chicago; Attending Surgeon to Cook County Hospital; Ex-President of Chicago Medical Society, etc. 1252

ANKYLOSIS. By R. A. Kinloch, M.D., Charleston, S.C., Professor of Surgery in the Medical College of the State of South Carolina; Surgeon to St. Xavier's Infirmary; Ex First Vice-President of the American Medical Association; Ex-President of the South Carolina Medical Association 1266

DEFORMITIES OF BONE. OSTEOCLASIS AND OSTEOTOMY. By A. G. Gerster, M.D., New York, Professor of Surgery, New York Polyclinic; Surgeon to the Mount Sinai and German Hospitals, etc. 1273

MECHANICAL TREATMENT OF DEFORMITIES OF INFANTILE PARALYSIS. By E. G. Brackett, M.D., Boston, Mass., Assistant Surgeon to the Out-Patient Department, Children's Hospital, Boston, etc. 1298

AMPUTATIONS. By William Barton Hopkins, M.D., Philadelphia, Pa., Senior Surgeon to the Episcopal Hospital; formerly Professor of Clinical Surgery, Philadelphia Polyclinic 1311

LIST OF ILLUSTRATIONS TO VOLUME III.

PLATES.

PAGES
Case showing Area of Flatness on Percussion when the Stomach is distended . . . between 44 and 45
Chart, Morbidity of "Cholera Infantum;" German Dispensary, New York, 1877–1887; 8036 Cases, and Average Monthly Temperature. (After Seibert) . . . " 66 and 67
Chart, Mortality of Diarrhœal Diseases in Children under Five Years of Age; New York City, 1877–1887; 31,048 Cases, and Average Monthly Temperature. (After Seibert) . . . " 66 and 67
Chart, Mortality of Diarrhœal Diseases in Children under Five Years of Age; Berlin, 1879–1883; 5131 Cases, with Mean Monthly Temperature. (After Baginsky) . . . " 68 and 69
Chart, Mortality from Diarrhœal Diseases in Children under Five Years of Age; Baltimore, 1879–1887; 4390 Cases, with Mean Monthly Temperature (Warm Months only). (After Miller) . . . " 68 and 69
Hyperplasia of the Lymph-Nodules (Solitary Follicles) of the Colon (Photo. I.) . . . " 84 and 85
Enlarged Lymph-Nodules (Solitary Follicles) of the Colon (Photo. II.) " 84 and 85
Superficial Ulcers of the Colon (Photo. III.) . . . " 84 and 85
Superficial Ulcers of the Colon (Photo. IV.) . . . " 84 and 85
Deep Follicular Ulcers of the Colon (Photo. V.) . . . " 84 and 85
Deep Sloughing Ulcers of the Colon (Photo. VI.) . . . " 84 and 85
Croupous Inflammation of the Ileum (Photo. VII.) . . . " 84 and 85
Chronic Hyperplasia of Lymph-Nodules of the Colon (Fig. 1) . . . " 86 and 87
Lymph-Nodule of the Colon in the Early Stage of Ulceration (Follicular Ulcer) (Fig. 2) . . . " 86 and 87
Deep Follicular Ulcer of the Colon (Fig. 3) . . . " 86 and 87
Broad Superficial Ulcer of the Colon (Fig. 4) . . . " 86 and 87
Acute Catarrhal Inflammation of the Ileum, Mild Form (Fig. 5) . . " 86 and 87
Acute Catarrhal Inflammation of the Ileum (Fig. 6) . . . " 86 and 87
Acute Catarrhal Colitis, Severe Form (Fig. 7) . . . " 86 and 87
Chronic Catarrhal Inflammation of the Ileum (Fig. 8) . . . " 86 and 87
Croupous Inflammation of the Colon (Fig. 9) . . . " 86 and 87
Poikilocytosis (Plate I., Fig. 1) . . . " 764 and 765
Melanæmia (Plate I., Fig. 2) . . . " 764 and 765
Blood in Relapsing Fever, showing the Spirillum (Plate I., Fig. 3) . . " 764 and 765
Blood in Leukæmia (Plate I., Fig. 4) . . . " 764 and 765
Blood from Case of Leukæmia, showing Eosinophilous Cells.—Ocular, Zentmeyer A, Objective, Zeiss $\frac{1}{12}$, Oil Immersion (Plate II., Fig. 8) . . . " 788 and 789

PAGES
Liver-Lobules in a Case of Pernicious Anæmia, showing Distribution of Iron Pigment.—Ocular, Zentmeyer A, Objective, Zentmeyer $\frac{8}{10}$ (Plate III., Fig. 11) . . . . between 816 and 817
Cells from Liver in Pernicious Anæmia, more highly magnified, showing Position of the Iron Pigment within them.—Ocular, Zentmeyer A, Objective, Zeiss $\frac{1}{12}$, Oil Immersion (Plate III., Fig. 12) . . . . " 816 and 817
Showing Scoliosis from Shortened Limb (Photo. 1) . . . . " 1004 and 1005
Showing Scoliosis corrected by equalizing the Pelvis (Photo. 2) . . " 1004 and 1005
Showing the Use of Self-Suspension, the Patient being in the Swing (Photo. 3) . . . . " 1014 and 1015
The Same Patient without Self-Suspension (Photo. 4) . . . . " 1014 and 1015
Cervical Caries (Plate I.) . . . . " 1028 and 1029
Taylor's Modification of Davis's Spinal Assistant (Plate II.) . . . " 1038 and 1039
Skeleton of Child about Five Months Old, showing the Large Size of the Cranium as compared with the Thorax and Pelvis, the Straightness and Small Size of the Bones of the Limbs, and the Epiphysial Condition of their Extremities (Plate I.) . . . . . " 1042 and 1043

FIGURES.

PAGE
Position of the Stomach and Liver in a Child of Two and a Half Months 46
Position of the Stomach in a Child of Four Months 47
Congenital Hernia, Testicle in 236
Funicular Hernia 236
Encysted Hernia 236
Funicular Hernia where the Process has closed at the Abdominal Ring 237
Truss of Berlin Wool 239
Vertical and Transverse Sections of an Intussusception 252
Narrowing of the Rectum or Anus without Complete Occlusion 322
Complete Occlusion of the Anus by a Membranous Diaphragm or by a Well-Formed Skin 323
Anus Absent and Rectum ending in a Blind Pouch at a Point more or less distant from the Perineum 324
Anus ends in a Cul-de-Sac; Rectum ends in a Blind Pouch 331
Rectum terminating in an Impervious Cord, the Anus being Normal 331
Rectum ends in a Cul-de-Sac; Anal Portion opens into the Vagina 332
Dissection of Child with Rectal Malformation; Death from Peritonitis following Rupture of the Transverse Colon 332
Anus Absent; Rectum ends in a Narrow Canal opening at the Prepuce 333
Anus Absent; Rectum terminates in the Posterior Wall of the Vagina 334
Anus Absent; Rectum terminates in the Bladder 335
Anus Absent; Rectum terminates in the Urethra 337
Vegetations around the Anus 340
Partial Prolapse of the Rectum 348
Complete Prolapse of the Rectum 348
Prolapse of the Rectum 349
Polypi of the Rectum 352
Embryo of Chick Four Days Old 367
Embryo of Chick Five Days Old 368
Larva of Frog 368
The Fœtal Circulation; Relative Position of the Organs 404

PAGE
Fused Kidney from a Child Three Years Old 517
Horse-Shoe Kidney from an Infant 518
Double Ureter of Left Kidney 519
Malposition of Left Kidney, with Other Abnormalities 521
Double Hilum on each Kidney, with Other Abnormalities 521
Pelvic Contents of Adult Male contrasted with those of a Male Child of Seven Years 601
Bladder pushed upward and forward by a Distended Rectum 619
Bigelow's Evacuator used in Litholapaxy 624
Otis Perfected Evacuator 626
Spurious Hermaphrodism 635
Penis shortened from a Contracted Prepuce 636
Phimosis with Elongated Prepuce 638
Stripping the Glans Penis 642
Levis's Dilating Forceps 643
Forceps for Use in Circumcision 644
The Operation of Circumcision 645
Slitting and Stitching of the Mucous Membrane after Circumcision 645
Operation by Incision 646
Phillips's Method of reducing Paraphimosis 647
Agnew's Method of reducing Paraphimosis 647
Division of a Paraphimosis 647
Hypospadia 648
Glans incurved by a Short Corpus Spongiosum 649
Redundant Prepuce partially concealing the Glans 651
Incisions for a New Urethra 651
Formation of a New Canal in Hypospadia 652
Schematic Plan of Four Flaps 652
Fistule in the Penile Part of the Urethra closed by Quilled Suture 655
Urethroplasty 655
Nélaton's Operation for closing a Urethral Fistule 655
Exstrophy with Epispadia 657
Operation for a New Canal 658
Artificial Urinary Receptacles 660
Hiatus of the Abdominal Wall, its Plastic Closure 661
Wood's Reverting Flap for Abdominal Hiatus 662
Roux and Maury's Operation for Abdominal Hiatus 662
Case of Spurious Hermaphrodism in a Male (two figures) 664
Female Organs simulating those of the Male Sex 667
Female Reproductive Organs in Childhood 713
Vulva and Associated Organs 714
Section of the Vagina 715
Müller's Ducts 742
Coalescence of Müller's Ducts 742
Disappearance of Septum in Coalesced Ducts 742
The Appearance of the Rudimentary Fundus and Cervix 742
Fœtal Uterus at Birth 743
Uterus at Birth 744
Cavities of Uterus at Birth 744
Uterus Bipartitus 744
Section of Uterus at Seventh Year 744
Uterus Unicornis of a Child 745
Uterus Didelphys 745
Uterus Bicornis Duplex 746
Uterus Bicornis Unicollis 746
Uterus Arcuatus 747

PAGE
Uterus Incudiformis 747
Uterus Septus Duplex 748
Hæmoglobinometer of Gowers 758
Hæmometer of Fleischl 759
Hæmacytometer of Thoma-Zeiss 760
Slide used in Counting Blood-Corpuscles 761
Blood-Cells in Lipæmia 765
Filaria Sanguinis Hominis 767
Bilharzia Hæmatobia 768
Photograph of Normal Blood 813
Photograph of Blood in Pernicious Anæmia 813
Artificial Respiration, Inspiratory Movement 848
Artificial Respiration, Expiratory Movement 848
Inhaler for Ether 916
Mode of using the Inhaler 917
Hypertrophy of Fingers 932
Absence of Fingers 935
Fusion of Digits 935
Supernumerary Finger 939
Supernumerary Thumb 940
Supernumerary Toe 940
Webbed Fingers 942
Norton's Operation for Webbed Fingers 942
Didot's Operation for Webbed Fingers 943
Didot's Operation; Transverse Section of Fingers 943
Noble Smith's Rod for Prevention of the Reunion of Fingers after the Operation for Webbed Digits 943
Rubber Cord for Prevention of the Reunion of Fingers after the Operation for Webbed Digits 943
Bilateral Congenital Dislocation of the Femora 948
The same case, showing Bilateral Dislocation of the Heads of the Radii, etc. . . . 948
Congenital Dislocation of the Tibia forward and outward 951
Posterior view of the foregoing case 951
Dorsal Surface of Club-Foot 958
Normal Astragalus, and Astragalus from a Club-Foot 959
Talipes Calcaneo-Valgus 961
Beely's Apparatus for Equino-Varus 965
The foregoing device applied 966
Taylor's Club-Foot Shoe 966
Taylor's Club-Foot Shoe applied 967
Taylor's Club-Foot Shoe modified to prevent Inversion or Eversion of the Foot or Toes 967
Lateral view of the foregoing 967
Extreme Deformity from Equino-Varus; four views of the same case 968
Morton's Apparatus for the Application of Extreme Force in Club-Foot 973
Club-Foot in a Girl of Eighteen treated by Extreme Force 974
Results in the foregoing case 974
A Club-Foot treated by Extreme Force 974
Result in the foregoing case, front view 975
The same, side view 975
Treatment of Club-Foot by the Excision of a Wedge-shaped Piece 976
Flat-Foot; Whitman's Device for its Treatment 977
The Usual Attitude in so-called Congenital Torticollis 982
Torticollis of Several Years' Duration, front view and rear view 983
Buckminster Brown's Appliance for Torticollis 987
Padded Metal Plate applied in a Case of Torticollis 987

Two Devices for Torticollis 988
Two Views showing the Application of a Simple Device for Moderate Torticollis . . 989
Case of Torticollis treated by an Operation 990
After-Treatment of the foregoing case 990
Results of Treatment in the foregoing case 991
Rachitic Scoliosis in a Case of Genu Valgum 1004
Rachitic Scoliosis to the Left, with Cyphosis 1005
Case of Torticollis showing Cervico-Dorsal Scoliosis 1005
Scoliosis from Empyema 1006
Scoliosis dependent on Myositis Ossificans 1006
High Dorsal Scoliosis from Infantile Cerebral Hemiplegia 1007
High Dorsal Scoliosis dependent upon Paralysis resulting from Polio-Myelitis . . . 1007
High Degree of Scoliosis with Cyphosis, the Result of Paralysis from Polio-Myelitis 1008
Lordosis with Slight Scoliosis in a Case of Paralysis of the Tranversalis and Oblique, resulting from Polio-Myelitis 1008
Diagram showing the Special Alterations in the Vertebræ in a Case of Spinal Curvature 1009
Early Stage of Scoliosis in a Small Child 1010
High Dorsal Scoliosis to the Right 1011
High Dorsal Scoliosis to the Left 1011
Lumbar Scoliosis to the Right, with compensating Dorsal Curve to the Left 1011
The most common form of Scoliosis,—Dorsal to the Right 1011
Dorsal Scoliosis to the Left in a Boy 1012
Right Dorsal Scoliosis, the patient bending forward to show the amount of rotation 1012
The Knight Brace for Lateral Curvature 1013
Barwell's Dorso-Lumbar Bandage, posterior view 1014
The same bandage, anterior view 1014
Barwell's Rotation Bandage, posterior view 1014
The same bandage, anterior view 1014
Extensive Erosion of Dorso-Lumbar Vertebræ 1021
Erosion of Lumbar Spine, Popliteal Abscess, without Deformity 1022
Characteristic Hunchback Deformity 1022
Marked Angular Curvature 1022
Dorsal Caries 1031
Functional Spinal Debility simulating Caries 1032
Lumbar Caries 1033
Davis's Spinal Assistant 1039
Diagram showing the Principle of Davis's Support 1039
Spinal Support with Chin-Rest 1041
Ball-and-Socket Joint for Chin-Rest 1041
Chin-Rest 1041
Development of the Osseous System in a Child about Seven Months Old 1043
The same in a Boy Four Years Old 1044
The same in a Boy Ten Years of Age 1044
Diagrams of Epiphyses (four figures) 1051
Barton's Bandage applied 1053
Pasteboard Splint for Chin 1056
Pasteboard Cup for Jaw 1056
Result after Multiple Fracture of Facial Bones 1058
Fracture of Lower Part of Humerus 1068
Pasteboard Splint for the above 1069
Normal Relation of Arm and Forearm in Extension and Supination 1073
Splint for Fracture near the Elbow 1073
Coover's Splint 1080
Splint for Fracture near Lower End of Radius 1081
Levis's Splint 1081

PAGE
Hamilton's Apparatus for Fractures of the Femur in Children 1087
Separation of Epiphysis of Femur 1091
Separation of Lower Epiphysis of Femur, with Fracture 1092
Weight-Extension acting as a Leverage in Disease of the Knee (four figures) . . . 1150
Diagram showing Abduction in Diseases of the Hip-Joint 1163
Diagram showing Apparent Lengthening in Hip-Joint Disease 1163
Diagram showing Adduction in Hip-Joint Disease 1163
Diagram illustrating Apparent Shortening in Hip-Joint Disease 1163
Case of Abduction in Hip-Joint Disease 1166
C. F. Taylor's Appliances for Hip-Joint Disease (two figures) 1178
Illustrations of Various Parts of Taylor's Hip-Splint (three figures) 1179
H. L. Taylor's Instrument for Correcting Adduction 1181
Thomas's Hip-Splint 1183
The same in use (two figures) 1184
Lovett's Apparatus for Hip-Joint Disease 1184
Cross-Leg or Scissor-Leg Deformity (two figures) 1187
Straight Incision over the Trochanter in Excision of Hip-Joint 1198
Anterior Incision for Excision of Hip-Joint 1201
Thomas's Splint for Tubercular Disease of Knee-Joint (two figures) 1213
Method of Resection of Shoulder-Joint by a Single Straight Anterior Incision . . . 1243
Position of Posterior Incision for Resection of the Shoulder 1243
Splint applied for Disease of Elbow-Joint 1245
Long Median Incision for Excision of the Elbow 1246
Gerster's Appliance for Use after Elbow-Excision ; Wristlet and Arm-Band 1247
View of the same fully applied 1248
Robin's Osteoclast 1276
Beely's Osteoclast 1277
Ferrari's Osteoclast 1278
Sayre's Knock-Knee Apparatus 1278
Adams's Saw 1281

OF THE
DISEASES OF CHILDREN.

PART I.
DISEASES OF THE DIGESTIVE SYSTEM.

FUNCTIONAL DISORDERS OF THE STOMACH.

By WILLIAM PEPPER, M.D., LL.D.

DYSPEPSIA.

THE group of disorders included under this heading are by some called the indigestions; by others the term infantile atrophy is used to designate many of them; while others describe them as acute and chronic gastric or gastro-intestinal catarrh.

It embraces all those clinical conditions, frequently presenting complicated symptoms, which are dependent upon impaired gastric digestion, provided that there is no lesion of the stomach more serious than congestion or subacute catarrhal inflammation.

Mere defects in quantity or quality of the gastric secretions, without any appreciable change in the gastric tissues, may cause temporary indigestion. Anæmia or impaired innervation will suffice to explain it. But the more carefully the dyspepsias of young children are studied, the more closely will they be found connected with varying degrees of gastric catarrh. While, therefore, it is convenient to consider under a separate heading acute catarrh of the stomach, it would involve excessive repetition to discuss the chronic form after having described catarrhal dyspepsia. The frequency of these disorders is even greater in children than in adults: they constitute by far the larger part of all chronic ailments in the former. The forms do not differ materially, but obviously it is less easy in children than in adults to classify individual cases of dyspepsia, as, for instance, atonic, nervous, or catarrhal. The chief reasons for this are the wide range of the sympathetic phenomena, the necessity of depending chiefly upon objective symptoms, the difficulty of studying critically the gastric secretions by means of lavage, and the frequency with which gastric catarrh sooner or later appears as an element in the case. Consequently, in this article the only division made will be into the acute and the chronic or habitual form of dyspepsia; and under each of these attention will be called to the peculiarities which present themselves in infants and in older children.

Causes.—Defects of feeding are the most common causes; but scarcely less important are errors in hygiene, especially concerning dress, exercise, bathing, and ventilation. Constitutional disorders, such as anæmia, rickets, scrofula, and lithæmia, often the result of inherited peculiarities, frequently act as predisposing causes. Close attention should be paid to the mode of action of these causes, as successful treatment invariably involves their detection and removal.

In suckling infants indigestion results chiefly, of course, from an unhealthy state of the milk of the nurse or from the premature use of artificial food. If the child has a wet-nurse the breast may be too old for the infant, or the health of the mother or nurse may be so poor that the quality of the milk suffers. It is not usual for the diet of a nursing woman to affect her milk materially, but it does in some cases; and if the child has indigestion this question should be examined. Fixed rules cannot be laid down on this subject. It may even happen that the breast is of the right age, the nurse's health excellent, and the milk of apparently good quality, and yet, owing to some peculiarity of the digestive juices of the child, indigestion results.

The supply of milk is often scanty, and then, without evident dyspeptic symptoms, a process of wasting or atrophy ensues, which may be mistaken for the result of indigestion. On the other hand, the supply may be excessive, and, if the nipple delivers it freely or the child sucks vigorously, an undue amount is swallowed. Usually the surplus is promptly rejected; and this form of vomiting or regurgitation is beneficial, and may avert the fermentation and gastric irritation which otherwise ensue.

More commonly the indigestion cannot be charged to the breast-milk, but is due to the fact that artificial food in undue proportion or of improper quality is given to the infant. Indeed, it seems a matter of wonder that more damage is not done, in view of the ignorant and reckless experimenting we often meet with. If the supply of breast-milk is actually scanty, the deficiency should be made up with cow's milk properly diluted and carefully sterilized. If, unfortunately, the mother cannot suckle her child, a wet-nurse is to be secured at once, if possible. If this is impracticable, the artificial diet to be used should be prescribed by the physician in accordance with the principles elsewhere formulated.

In older children also, dietetic errors are frequent causes of dyspepsia. The mastication of the food now becomes of great importance. If this essential element in normal digestion is neglected, gastric disorder must sooner or later be induced. Irregularity of meals, undue variety of food, the premature use of tea, coffee, or spices, the unlimited use of ice-water, of fruit, or of sweets, the pernicious habit of eating candy, cake, or fruit between meals,—such errors are responsible for a vast amount of dyspepsia in childhood, and for an infinity of ill health subsequently.

But neither at this age nor in infants are dietetic errors to be regarded as the sole causes of the indigestions which are of such common occurrence. A vigorous stomach will tolerate much abuse even at an early age. But if the mucous membrane has been repeatedly congested, owing to sudden checking of the cutaneous circulation from imprudent exposure, from insufficient clothing, or from too rapid cooling of the body when overheated by play, a condition of weakness and irritability is developed which enables comparatively slight dietetic errors to produce severe symptoms, and which goes on rapidly to the establishment of subacute catarrh. It is enough to mention such causes to insure a recognition of their frequent operation.

It must further be remembered that at all periods of childhood there is great liability to the predisposing causes of dyspepsia. The inheritance of anatomical or physiological defects may show itself in this way. A scrofulous or gouty or rheumatic diathesis may dispose to faults of digestion and of assimilation. The neglect of sanitary precautions as to air, light, exercise, the depressing influence of dentition, and the exhausting drain of rapid growth and development, reduce nervous force and resisting power, and favor derangement of the complicated functions of digestion. The acute ailments and the specific fevers so common in childhood are apt to leave behind extreme sensitiveness of the system, and especially of the alimentary mucous membrane, even if a catarrhal process has not, as is often the case, been initiated. Such considerations indicate the varied nature of the causes of dyspepsia in childhood and impress strongly the need of constant vigilance to avoid its occurrence.

Pathology.—As already stated, there must be recognized in many cases of dyspepsia a state of lowered nervous force. This of itself may directly induce digestive failure, or it may merely serve to predispose thereto; while in all cases the nervous debility will be increased by the lack of assimilation and by the drain due to the prolonged reflex irritation. There exist also defects, quantitative and qualitative, in the gastric secretions, which are doubtless analogous to those with which we are becoming familiar from recent chemical studies in the dyspepsias of adults. There are marked and important variations in the blood-supply, and in the tonicity of the gastric walls and especially of the muscular layer. Lastly, and most serious of all, there are the lesions of catarrhal inflammation. The mucous membrane becomes congested in patches: it is somewhat thickened, and in some cases the follicles are enlarged so as to give an appearance of slight roughness to the surface when viewed obliquely. The consistence of the membrane may be diminished, though much care is needed to avoid confounding this with the results of post-mortem maceration, which explains most of the softening of the stomach. On the other hand, in severe cases of long-standing catarrh the mucous membrane is of a grayish or light slate color and may be thicker and firmer than normal. The secretion of mucus is increased; the surface is covered with thick and tenacious layers of it. On the other hand, the gastric juice is apt to be lessened in amount, or at least to be deficient in peptic strength. The impairment of the muscular tone of the walls, and the fermentation of the mucus and food which the stomach contains, often induce dilatation even to marked degrees.

Symptoms.—Acute or accidental indigestion in infants causes weakness, with pallor of the face, and restlessness, with moaning cries or with screaming at the least disturbance. The skin may be hot and dry, or there may be nausea, with a relaxed, cool surface. Sleep is broken and restless. The abdomen is distended with flatus and the epigastrium is tender. Vomiting of sour, curdled milk occurs, and is followed by relief. The attack may be cut short when the stomach is thus emptied; but if the irritation of the mucous membrane is greater, vomiting will continue, and the matter rejected, with painful retching, will consist of bile-stained, watery mucus. Some elevation of temperature (101° or 102° F.) will occur in these cases for a short time. The bowels are usually constipated, but towards the close of the attack some diarrhœa may occur, either because undigested food has passed into the intestines or because the intestinal mucous membrane also has been affected by the imprudent exposure which produced the attack. The symptoms subside in from twenty-four to sixty hours, but the stomach remains sensitive for a few days longer.

In older children these attacks may be more severe, especially if, in addition to the irritation caused by indigestible and fermenting food, there are, as so often happens, congestion and catarrh of the stomach produced by atmospheric influences. To these more serious attacks a separate section is devoted, under the heading of Acute Gastric Catarrh (see page 33).

There are, however, many mild cases, of short duration and with slight general disturbance. Within a few hours or a day after eating excessively or imprudently, the child becomes languid and chilly, grows drowsy, and complains of headache and pain in the stomach. If vomiting, fortunately, occur, the attack may be promptly broken up, just as in infants. But if the offending matters are retained, fever ensues, with rapid, bounding pulse, hot, dry skin, tender, full epigastrium, coated tongue, and marked thirst. The bowels are constipated; the urine is scanty, high-colored, and turbid. Such symptoms gradually subside, the stomach regains its tone, and appetite returns: the child remains weak and pale for a few days, but regains its usual health in the course of three to six days. If the child has a predisposition to convulsions, such attacks may induce them. I have known a number of children who for several years had occasional spells of acute dyspepsia, and had one or more convulsions with each such spell, until by the adoption of suitable hygienic rules the disturbances of digestion were avoided and the convulsions did not recur. In certain families this association has shown itself in several children successively, in consequence either of undue nervous mobility or of a tendency to lithæmia with the production of irritating ptomaines. These severe nervous symptoms may attend gastric attacks of apparent mildness. They are due more to the predisposing tendency than to the gravity of the exciting cause.

Chronic dyspepsia or habitual indigestion occurs likewise at all ages. It may exist almost from birth, or come on insidiously at a later date; but in many cases it is preceded by a series of attacks of acute indigestion, occurring at shorter and shorter intervals and induced by milder and milder causes as the resisting power of the system is reduced and the mucous membrane of the stomach becomes more constantly the seat of catarrhal irritation, with impairment of its functions.

The effect upon the child varies much, according to the amount of nourishment which, though with difficulty and distress, is extracted from the food ingested. Some children despite marked dyspeptic symptoms grow fairly well, though they become pale and flabby. But others are unable to keep pace with the demands on their nutrition, and grow thin, with pinched cheeks, projecting cheek-bones, and small muscles, though the abdomen may appear full, owing to flatulent distention. The most extreme degrees of atrophy or wasting are seen in puny infants who are fed on an insufficient amount of milk with large admixture of inappropriate starchy food. Still, we may encounter in older children startling degrees of emaciation, such as Gull has described under the name of anorexia nervosa, dependent solely upon chronic catarrhal dyspepsia.

Young infants with habitual indigestion sleep badly, are peevish, and often cry violently: they are especially restless and troublesome at night. The skin is pale, wrinkled, and not rarely presents eruptions. The extremities are cool; the fontanel is level or depressed. The appetite may be impaired, so that the child can be fed only with great difficulty; or there may be a craving thirst or appetite which leads him to take ravenously whatever is offered, even though its reception quickly causes increased gastric distress, with painful colic, nausea, or vomiting. The tongue is not so characteristically affected as in older children: usually it is moist, flabby, and coated whitish. The bowels are apt to be constipated, as a rule; and the movements may be abnormally dry and hard, so as to be expelled with effort and pain. From time to time short spells of diarrhœa occur, and then the stools are of partly-undigested food, bile-stained and with an increased amount of mucus. Vomiting is an almost constant symptom, but varies greatly in character and frequency. It may occur but occasionally, when the stomach gets overloaded, or when the food disagrees more than commonly; or it may be the most troublesome and dangerous symptom. The acts of vomiting are very frequent: as soon as food is taken, more or less of it is rejected, and in the intervals bile-stained, watery mucus is thrown up. Such spells of persistent vomiting require prompt and judicious treatment. They are very debilitating, and, unless checked, the familiar hydrocephaloid symptoms of cerebral anæmia and exhaustion may appear and be followed by death.

The symptoms of habitual indigestion in older children are analogous to those observed in the adult. With a varying amount of malnutrition and interference with growth, or of actual emaciation, the appearance is one of languor, weakness, and debility. The child is indifferent to play, or else plays violently and spasmodically and soon grows weary. The temper is perverted, irritable, and uncertain. The breath is heavy and unpleasant. The tongue is usually large, flabby, tooth-marked, and covered with a coating white and thin in front and thicker and more yellowish towards the base, while the papillæ are enlarged, reddened, and prominent. In some cases the tongue presents denuded areas of limited size and circular or irregularly curved in shape, which may be seated in the centre or on either half of the organ. The appetite is variable, and often perverted. There is feeble or absent desire for suitable food at usual hours, while the child craves sweets or highly-seasoned articles at odd times. There may even be genuine boulimia, with insatiate craving for all sorts of food, and even when large amounts have been taken there is no sense of relief or satisfaction. The irritation is often referred to the nostrils or to the anus, so that the child is instinctively and uncontrollably picking the nose or clutching at his seat. In accordance with tradition, such symptoms are held to denote the presence of intestinal worms; and, in fact, it is by no means rare for ascarides to appear in such cases.

Nausea is often complained of, or may be determined to exist by the expression of face and the attendant debility and relaxation in children too young to interpret their sensations. Vomiting is much less common than in the habitual indigestion of infants; but from time to time there is apt to be an exacerbation of the catarrh, from some atmospheric or dietetic cause, and then the stomach grows more irritable and vomiting occurs. The matters rejected are acid, and composed of partially-digested fermenting food, with tenacious glairy mucus. There is no reason to doubt that the chemical changes in the gastric contents are similar to those found in adults suffering with the various forms of dyspepsia, although this question has not yet been fully studied in children. There seems to be, however, an especial tendency to loss of peptic strength from failure in the secretion of the digestive principles, and to hyperacidity, probably more from the development of secondary organic acids than from excess of hydrochloric acid. When the obstacles to removal of gastric contents by lavage can be overcome, it is important to secure careful chemical and microscopical examinations. I must state, however, that in my own experience, in private practice, it has proved very difficult to use lavage in young children, for purposes either of diagnosis or of treatment.

The bowels are habitually constipated, and the stools present unhealthy appearances. Several days may intervene between passages, which consist of a few hard balls, clayish or party-colored, and smeared with stringy mucus. In such cases the intestinal secretions are scanty, the abdominal and intestinal walls are weak, and the colon and its pouches are dilated. Or, on the other hand, the stools may be of mushy consistence, and present under the microscope many fragments of undigested food and many oil-globules. Indeed, it is impossible to describe all the variations, since the gastric disorder is so often associated with similar morbid conditions of the intestines, and since the intercurrent attacks of renewed gastric irritation are usually attended with more or less intestinal catarrh.

Flatulence is a constant symptom. There may be eructations; the belly is distended, and there are frequent colicky pains. The fulness may be limited to the epigastrium or be general and so considerable as to make the body contrast sharply with the thin features and limbs. Dilatation of the stomach is a common attendant upon this atonic type of dyspepsia if severe and long continued. It may be expected to occur in a moderate and unimportant degree, but extreme care must be used to avoid mistaking mere flatulent distention of the stomach and intestines for true persistent and organic dilatation. The reader is referred to the account of this latter condition (see page 41); but, as there shown, it is by no means rare for such dilatation even of high degree to develop in the course of chronic gastric catarrh, especially in rachitic children and in those who have marked nervous adynamia and muscular atony. I am disposed to attach a far greater degree of importance than is usually assigned to this condition in the dyspepsias, catarrhal and atonic, of children, both as regards the production of symptoms and as affecting the results of treatment.

Pain is present in most cases. It may be only a sense of distress referred vaguely to the abdomen, and varied by spells of acute flatulent colic occurring a couple of hours after meals. Or the neurotic or neuralgic element may be much more prominent, and violent paroxysms of abdominal pain may occur at irregular intervals, which must be regarded as gastralgia or enteralgia. It will, of course, be remembered that young children are often unable to locate sufferings, so that it may be necessary to determine the seat of pain by exclusion,—by a study of the physiognomy and movements; just as, on the other hand, I have repeatedly known the pain of pleurisy or of rheumatic pericarditis to be referred to the abdomen by the little sufferer. In children, as in adults, there are dyspepsias which deserve the name of nervous, from a mere clinical stand-point, on account of the predominance of the symptoms of local or reflex nervous irritation. In addition to the neuralgic paroxysms above mentioned, there occur in different cases reflex disturbances of the heart's action, spells of extraordinarily rapid breathing, due to a species of palpitation of the diaphragm, attacks of syncope, closely simulating *petit mal*, choreic twitching of muscles, or even, as already mentioned, general convulsions when, from time to time, the gastric irritation is increased by fresh catarrhal attacks.

Perversions of temper and of disposition are common; and it is certain that many young dyspeptics are wholly misunderstood and are unwisely and unjustly punished for faults which are attributable to their disordered digestion and nerves. The sleep is rarely quiet and refreshing. The child rolls and tosses; twitchings of the muscles, sudden startings, and grinding of the teeth occur. Nightmare is frequently repeated. Less common are such attacks of temporary aphasia as are alluded to at page 37, or attacks of hysterical excitement during the day, with alarming visions as of fierce dogs or of wild animals, such as I have met with in several cases.

Fever is much more apt to attend dyspeptic troubles in children than in adults. In simple inanition of infants and in the advanced stages of atonic dyspepsia the temperature often falls even below normal. On the other hand, we have seen that acute attacks of indigestion at all ages are apt to be attended with fever, and also that in the course of chronic dyspepsia febrile exacerbations of catarrh are of common occurrence. But, moreover, it is not at all times uncommon to find in the morning or towards evening a slight elevation of the sublingual or rectal temperature in children who are the subjects of habitual indigestion of irritative type. This is more surely the case in scrofulous or rachitic subjects; but careful study will often show, when not suspected, that an element of slow fever is added to the other influences which are depressing the nutrition. It is, of course, most marked in cases where the subacute catarrh of the mucous membrane is most pronounced, and especially if at the same time the intestinal mucous membrane is invaded. These aggravated cases of chronic gastric or gastro-intestinal catarrh, to which the name of the mucous disease has long been applied, are the most serious form of habitual indigestion in children.

The tongue indicates the greater degree of the irritation of the mucous membrane. It is heavily coated, with prominent papillæ; or the fur is lighter and there are sharply circumscribed bare patches; or the entire dorsum is denuded, red and glazed in appearance. The gastric irritability and the abdominal distress are pronounced; the matters vomited contain a great deal of tough mucus, and the stools may habitually show its presence, although this is much increased with the fresh catarrhal attacks, which are of frequent occurrence and are attended with both vomiting and purging. The reflex nervous symptoms and the disturbances of general health are correspondingly marked. Debility and emaciation are extreme; there is apt to be some elevation of temperature; and during the exacerbations of catarrhal irritation there is for several days at a time quite high fever (101½° to 103° F.). The pulse is habitually quickened. The urine varies much in appearance and quantity, and not rarely presents evidences of vesical catarrh in the form of leucocytes, epithelial cells, and probably a trace of albumen. Catarrhal irritation of other mucous membranes, as of the nose and throat or of the bronchi, is apt to occur from time to time, showing that morbid sensitiveness of the epithelial structures and a lowered resisting power of the system are at the root of the trouble. Such children are peculiarly liable to intercurrent diseases; and although even the grave forms of dyspepsia are not in themselves often fatal, save in young infants, they cause such constitutional debility as to invite more dangerous acute disease or pave the way for tuberculosis in later years.

Diagnosis.—The diagnosis of the indigestions in children presents no serious difficulties, save that it is occasionally necessary to wait for some hours or even a day or two before it is possible to exclude the initial stage of all specific fevers. Acute attacks in infants are easily recognizable by the suddenness of the onset, the character and quantity of the matter vomited, the prompt relief when the stomach is emptied, and the rapid recovery. In older children the high fever, rapid pulse, hot flushed skin, and nervous symptoms which attend such acute spells of indigestion may readily lead to a suspicion of scarlet fever. The fever and acceleration of pulse are, however, less marked; sore throat and enlargement of the tonsils and of the glands at the angles of the jaw are wanting; and the transient erythema which may be present lacks the characteristic details of the scarlatinous eruption. At the most, it can only be necessary to delay decision and to pursue expectant symptomatic treatment for twelve or twenty-four hours. The onset of acute tonsillitis, of nephritis, or even of pneumonia may be overlooked, and the attack be regarded as one of acute gastric catarrh, owing to the decided gastric symptoms and the inability of the child to direct attention to the seat of trouble. Such palpable blunders as these cannot be avoided unless the one safe plan be followed of examining the throat, the urine, and the chest in every case of acute disease, without regard to the special symptoms, before forming a final diagnosis or adopting a comprehensive plan of treatment.

The important question of diagnosis between the most severe cases of subacute gastric catarrh and typhoid fever is fully considered in the article upon the former affection.

The habitual indigestion of infants can rarely be mistaken for any other disease. The chief source of danger is that some intercurrent disease, as subacute catarrhal pneumonia, pleurisy, or pulmonary collapse, may be developed insidiously and escape detection. The careful examination, from time to time, of all the important organs of the body must, therefore, never be omitted.

The question of hereditary syphilis must, however, be entertained, and the exclusion of the possibility of this taint may be somewhat difficult. Infants who are the subjects of inherited syphilis are often puny, weak, and emaciated, with dry wrinkled skin, just as are the subjects of infantile atrophy from habitual indigestion. But the signs of nasal catarrh, the peculiar parchment-like appearance of the skin, with scattered coppery spots, the mucous tubercles and rhagades or fissures at the corners of the mouth, the enlargement of the spleen, and the information elicited from the parents, will nearly always enable a diagnosis to be made. It is especially important to decide this question without having recourse to the therapeutic test of specific treatment, since effective doses of iodide of potassium or of any preparation of mercury are likely to be injurious if the case is not syphilitic. Still, I have met with cases where, after the most careful balancing of probabilities, a degree of doubt remained which could be dispelled in no other way than by an experimental course of antisyphilitic medication. I should advise mercurial inunctions in such cases, in preference to remedies administered internally.

When tuberculosis occurs in the infant, the temperature is elevated, and the thermometer in the rectum will show a maximum in the evening or morning (for the febrile movements of young children frequently reach the highest point in the morning) of 101° or 103° F.; there are apt to be signs of pulmonary trouble at least in the form of scattered râles or areas of altered respiratory murmur; and diarrhœa commonly ensues, owing to tuberculosis of the intestinal mucous membrane. These symptoms clearly distinguish it from ordinary infantile atrophy, which is attended with no elevation or even with a depression of temperature. Yet it is evident that such infants are liable to more or less wide-spread catarrh, and that when this affects the bronchial and intestinal mucous membrane a condition develops which will closely simulate tuberculosis. The absence of sputa, and the unsatisfactory result of microscopic search for tuberculous bacilli in the stools, further increase the difficulty of positive diagnosis, until the temporary aggravation of the dyspeptic symptoms has subsided.

In older children chronic dyspepsia is usually recognized with ease. The commonest error in diagnosis is undoubtedly the failure to detect the gastric origin of certain reflex symptoms or of the disturbances of general health. Allusion has already been made to the question which is almost sure to be raised as to the possibility of explaining the symptoms by the presence of intestinal worms. It will not suffice to give assurances that if worms are present they are to be regarded as the result of defective digestion rather than as the cause of the symptoms present. Nor must it be forgotten that in certain cases intestinal parasites do actually cause decided and varied symptoms. It may be altogether proper, therefore, to eliminate this element by the administration of efficient but unirritating vermifuges.

Careful examination must always be made of the heart and of the urine, since cardiac and renal diseases are as fruitful sources of indigestion in children as in adults. Cirrhosis of the liver in children is so rare that it is enough to refer to it with the remark that during its earlier stages the more evident symptoms are those of gastric congestion and catarrh. But hepatic congestion and catarrh are, on the other hand, of frequent occurrence in childhood, and have close relations with the dyspepsias. The affection of the liver may be primary and the gastric disorder secondary and dependent. But much more frequently the trouble has arisen as a gastro-duodenal catarrh which has invaded the bile-ducts more or less deeply. This is the usual significance of jaundice when occurring in dyspeptic children; and in many cases it is necessary to appreciate the coexistence of hepatic irritation even when no such decided symptoms as jaundice have been produced. The diagnosis of gastric ulcer and of dilatation of the stomach is considered under these respective headings.

In severe cases, with marked impairment of general health, with frequently-recurring spells of fever and increased catarrhal irritation, with attenuated features and limbs and distended abdomen, and especially with the addition of bronchial catarrh easily explicable by the undue sensibility of the system, the fear of tuberculosis is likely to arise. A correct diagnosis may, however, be made by careful attention to the history of the case and to the sequence in which the symptoms have appeared; to the facts that the recurring spells of increased catarrh can be traced to definite atmospheric or dietetic causes, and that the fever is proportionate in intensity and duration to the gastro-intestinal irritation, and in the intervals between the spells disappears or is marked only by a trifling rise in the morning or evening; to the peculiar changes presented by the tongue, by the matters vomited, and by the stools; to the fugitive and shifting character of the physical signs of chest-trouble; to the absence of splenic enlargement, which often occurs in tuberculosis; and, finally, to the gratifying results of proper hygienic and medical treatment.

Prognosis.—Dyspepsia in children, when primary and unassociated with organic disease, yields to treatment, as a rule. There are, however, infants who have inherited such feeble vitality and digestion that it is well-nigh impossible to save them; nor, if their lives are spared, do they ever attain vigorous health. Trifling intercurrent affections may abruptly cut short the course of habitual indigestion in such frail subjects. There are at times unfavorable hygienic conditions, beyond the power of the physician to rectify, which will defeat the most judicious treatment, so that the case advances to hopeless atrophy and vital exhaustion.

An excessive mobility of the nervous system may allow convulsions to result from the gastric irritation, and serious or even fatal consequences may follow. The protracted disorder of nutrition, especially in the more severe cases of gastro-intestinal catarrh, may invite the development of a tuberculous tendency, and exposes the child to the danger of attacks of jaundice, of nephritis, or of catarrhal pneumonia. The acute infectious diseases are not necessarily more severe or fatal in children suffering thus than in those enjoying vigorous health.

While, therefore, the dyspepsias of children are not of themselves often fatal, they are serious on account of the vulnerability of system they induce; they are prone to recur; and they are apt to interfere with normal development and to entail subsequent debility of digestion, of nerve, or of the entire nutrition.

Treatment.—Some of the important questions connected with the management of indigestion in the infant and in the older child cannot be adequately treated here, owing to want of space. No attempt will, for instance, be made here to discuss exhaustively all the details of the hygienic and dietetic management which is essential to prevent disorders of digestion, and which constitutes the most important part of the treatment of these disorders when they have, unfortunately, been allowed to develop. It is not too much to assert that when strict and intelligent care is used, and when the environment is reasonably favorable, the task of keeping in order the digestion of infants, whether suckled or fed artificially, and of children at all ages, is a comparatively easy one. But neither the prevention nor the cure of the dyspepsias will be possible unless the principle is clearly appreciated and persistently applied that minute attention to every detail of life—dress, bathing, ventilation, rest, and exercise, as well as diet—is the price of success in managing children.

The treatment of acute dyspepsia or occasional indigestion in infants is very simple. Sufficient vomiting has usually occurred before the child is seen by the physician, and the only indication is to allay gastric irritation and to prevent exhaustion. The child should be held quietly upon the lap or placed in bed, the room darkened, and everything avoided which can arouse the attention. After each act of vomiting there may be such signs of relief that the nurse is encouraged to try to amuse the child; but all such interference is exhausting and helps to induce further spells of vomiting. A small mustard plaster weakened with flour, a spice plaster, a warm mush poultice, or a flannel cloth wrung out of hot water and spirit, should be applied over the stomach. For some hours there is no desire for food; and no attempt should be made to force feeding. Thirst may be allayed by scraps of ice, or by a few drops of a mixture of equal parts of lime-water and cinnamon-water, or of milk and lime-water, given at short intervals. This will also serve to settle the stomach, and gradually the amount may be increased as the child can take and retain it.

But if vomiting persists it is worse than useless to persist with efforts to administer food. An enema of one to four teaspoonfuls of tepid water containing a proper amount of deodorized tincture of opium (from one-half drop upward, according to the age) should be given to allay restlessness and irritability. The infant will, as a rule, promptly return to the breast or to its usual food as soon as the vomiting is allayed. Should the child continue restless and fretful, with coated tongue, and full and tender belly, it is due to the passage of fermenting and indigestible food into the bowels. Under these circumstances, an evacuation should be encouraged, either by a suppository of gluten or glycerin, or by a simple laxative, if the stomach be prepared for it, of castor oil in delicate emulsion, or of calcined magnesia in spiced syrup of rhubarb.

In older children it more frequently happens that the stomach does not at once reject all of the offending matters: so that if vomiting has not occurred, or seems to have been inadequate, it is important to secure the full evacuation of the stomach by draughts of warm water or by ipecacuanha. This preliminary is too often neglected; but, on the other hand, nothing must be given which can increase the already existing irritation. The attack is, as we have seen, likely to be attended with fever, and may be protracted for several days. The child is, therefore, to be at once put to bed and to be strictly confined there until fully convalescent. Counter-irritation at the epigastrium by mustard or iodine is useful. Food is to be withheld entirely for several hours. If the stomach remains irritable and non-retentive after that, it may be well to give nutritious enemas, especially if the child is delicate. The chief indications are to allay gastric irritation, to prevent fever, and to promote gentle action of the bowels. If the febrile reaction seems likely to be marked, it is well to give, every two hours, small amounts of freshly-prepared effervescing draught, each dose containing a fraction of a drop of tincture of aconite root; or of liquid effervescing citrate of magnesia (f℥ss to f℥i). If the stomach does not retain these, and especially if the tongue is heavily coated, it is better to resort to divided doses of calomel (gr. $\frac{1}{20}$ to gr. $\frac{1}{12}$) mixed with minute amounts of bicarbonate of sodium, subnitrate of bismuth, or sugar of milk. One such powder may be placed dry on the tongue every second hour; and at the intervening hour a dose of aconite (gtt. $\frac{1}{4}$ to gtt. $\frac{1}{2}$) may be given in a teaspoonful of hot water or of iced carbonic-acid-water. The laxative action of these remedies is to be promoted by a suppository of gluten or glycerin or by a laxative enema. Desirable as it is to secure a movement of the bowels, it must be remembered that, in the exquisitely sensitive state of the stomach, any active laxative in ordinary dose would inevitably increase irritation and prolong the case.

As the stomach grows settled, food is to be given at first in teaspoonful doses of milk and lime-water or of milk and carbonic-acid-water, repeated at short intervals. Gradually the amounts can be increased, light broths added, and thus a return to ordinary diet slowly effected. Any tendency to marked nervous symptoms, such as severe headache, or excessive restlessness, or twitching or jerking of the muscles, should be controlled by an enema of chloral hydrate (gr. v in f℥i of water at three years of age) with or without bromide of potassium or laudanum associated. If there is high fever, attended with such symptoms, a warm bath will exert a soothing influence; and a dose of effervescing granulated sodium salicylate and antipyrin (ʒi = āā gr. ii) in a small amount of water will act promptly and most agreeably. For some days after the attack, unusual care is to be observed as to diet, exercise, and exposure; and it is well to administer a digestive tonic, such as

℞ Fairchild's essence of pepsin,
Fairchild's diastatic pancreatic extract, āā, f℥ iss.
M. S.—From one-half to one small teaspoonful in a little water after meals.

Or

℞ Elix. bismuth, pepsin, and strychnine.
S.—From fifteen to thirty drops in water after meals.

Or

℞ Quininæ sulph., gr. xii;
Strychninæ, gr. $\frac{1}{5}$;
Acidi sulphurici aromatici, fʒi;
Curaçoæ vel Elix. simplicis, fʒiii;
Aquæ puræ, q. s. ad f℥iii
Ft. sol.
S.—From thirty to sixty drops in water after meals.

These doses, as is the case with all others suggested in this article, are adapted to children of from three to seven years.

In the treatment of the habitual indigestion of infants, the first thing demanded is a careful study of the diet. If the child is still nursing, the breast-milk must be examined critically as to quantity and quality. If decided defects are found, it is desirable to lose no time in securing another breast of milk, if possible. But it may happen that the infant cannot or will not suckle, or that the best breast-milk disagrees. The child must then be weaned, and the problem of artificial feeding is presented. It is best in all cases to have recourse to cow's milk, carefully selected, and properly diluted with water, lime-water, or barley-water. For an infant a few months old the milk should not be more than one-half strength, and if this disagrees the proportion of milk should be further reduced. Often the simple fact that the milk is properly diluted and is administered in small quantities at proper intervals will put a stop to the vomiting and the infant will begin to improve. But if the food continues to ferment, and vomiting and distress still occur, a mixture of whey f℥i, fresh cream f℥ss, and water f℥i, may be tried, or a mixture of strippings (obtained by re-milking the cow) with water; or delicate broths made of chicken, veal, or beef, and mixed with equal amounts of rice- or barley-water. In cases of this kind, a diet consisting of gelatin, milk, cream, and arrow-root, as recommended in Meigs and Pepper on Diseases of Children, may be found to suit better than anything else. The amount to be given at each feeding must be carefully adapted to the age, and to the digestive power of the stomach. The food must be prepared with great care, and be kept so as to avoid all risk of contamination or of fermentation. It cannot be doubted that the process of sterilizing all milk used in the preparation of artificial food for infants is highly important as excluding micro-organisms and fermentation, while at the same time it permits a larger amount of the food to be prepared at once and thus saves much trouble.

It is equally essential to promote healthy action of the skin, and thoroughly to protect the body by proper clothing from undue atmospheric influences. Bathing should be replaced by sponging the body daily with warm water, to which a very little ammonia or salt or alcohol may be added. This is to be followed by gentle but thorough inunction with olive or cod-liver oil. It is doubtful whether the latter has any greater value to compensate for the offensive odor which it imparts. But there can be no doubt as to the positive beneficial effect of such inunctions when used perseveringly. A light flannel binder is to be kept around the abdomen. The infant is to be dressed from neck to toes in woollen garments of appropriate weight.

When this is done it is possible to keep the temperature of the room down to 69° or 70° F., and to admit fresh air so as to keep the apartment pure and healthy. This is far safer and better than to have the body-clothing too light for protection and to depend upon extra wraps and upon keeping the room very warm. The little child is rendered more tender and susceptible, and the utmost care is unable to avoid draughts and changes of temperature which will then certainly give colds.

The main indications for the administration of medicines are to allay vomiting, to improve digestion, and to promote nutrition. It is needless to say that all medication is secondary to dietetics and hygiene, and that the remedies selected must be given cautiously, in small doses, and in palatable forms. It is often found, even when it could scarcely be expected, that cod-liver oil is well received and digested. It then proves of the utmost value, and remarkable improvement follows its use. It is best given in the form of a delicate freshly-made emulsion with lacto-phosphate of lime, as follows:

℞ Ol. jec. aselli, f℥iss;
Calcis lacto-phosphatis, gr. xxxii;
Pulv. acaciæ,
Sacchari lactis, āā, q. s.;
Ol. cinnamomi vel Ol. gaultheriæ, gtt. iii;
Aquæ puræ, q. s. ad f℥iv.
Ft. mist. sec. art.
S.—A teaspoonful three times daily for an infant four months old.

It must not be imagined that even the most delicately prepared emulsions will always be received. On the contrary, there are cases where the most minute amount will disagree. It may be found then that extremely small doses of arsenic will do better: as, for instance,—

℞ Liq. arsenici chloridi, gtt. xvi;
Acidi muriatici diluti, gtt. xvi;
Aquæ cinnamomi, q. s. ad f℥iv.
M. S.—From twenty to sixty drops in a teaspoonful of water after food, three or four times daily.

Or if an alkaline preparation be preferred,—

℞ Liq. potassæ arsenitis, gr. xvi;
Sodii bicarbonatis, gr. xxxii;
Aquæ cinnamomi, q. s. ad f℥iv;
M. S.—From twenty to sixty drops in a teaspoonful of water after food, three or four times daily.

Other aromatic waters may be used as the vehicle, or it may answer better to use simple distilled water.

These remedies have the advantage that if they act favorably on the mucous membrane they will exert a good influence upon the general nutrition. But it often happens that even these small doses of arsenic cause irritation, or at least do not allay that which already exists.

There is no remedy which can be given, even to the youngest infants, with more confidence than nitrate of silver in those cases where the gastric irritability is excessive, so that vomiting is a chronic condition. The dose must be very small, at the beginning at least, as, for instance:

℞ Argenti nitratis, gr. $\frac{1}{2}$;
Aquæ destillatæ, f℥v.
Ft. sol.

S.—From thirty to sixty drops in a teaspoonful of water to a child six months old, four times daily, on an empty stomach.

Indeed, in all the catarrhal affections of the gastro-intestinal mucous membrane in children this remedy possesses remarkable value, although it requires great tact to determine the dose and the frequency and times of administration best adapted to each case.

From time to time, in spite of strict care, exacerbations of the symptoms may occur; and it will then be well to omit the standard remedies and to use a brief course of minute doses of calomel (gr. $\frac{1}{20}$ to gr. $\frac{1}{12}$ every two hours), followed for a few days by drop doses of wine of ipecac every four hours, or by powders containing,—

℞ Pepsin. (saccharated),
Bismuth. subnitratis, āā, gr. x ad gr. xx.
M. et div. in chart. xx.
S.—One three or six times daily.

Throughout the course of the case the degree of weakness may be such at any time as to call for stimulants. When required, only carefully-selected wines, such as old port or old dry sherry, or the best whiskey or brandy, should be used; and these are to be given in small doses and freely diluted, and their use is to be suspended as soon as may be deemed prudent. The prolonged use of stimulants in cases of habitual indigestion is rarely beneficial, and is not without danger of increasing the digestive trouble.

As the condition of the stomach and the power of taking food improve, it may be found that nothing more is needed than a continuance of the cod-liver oil or of the arsenic; but commonly it is better to substitute for them or to add to them small doses of iron, with quinine or strychnine. Indeed, it is sometimes found at an earlier stage of the case, when the anæmia and wasting are marked but the stomach is not very irritable, that very small doses of iron, in the form of the syrup of the iodide or the tincture of the chloride, or combined with vegetable bitters, as in the ferrated elixirs of gentian or cinchona, are well borne and digested, and are productive of distinct benefit.

Much of what has been said is applicable to the management of the habitual indigestion of older children. The same care is demanded as to their dress, bathing, rest and exercise, and diet. I am happy to believe that it is not as necessary to insist upon the primary and supreme importance of these things, now that the claims of hygiene are widely recognized, as it was twenty years ago. But it is impossible too often or too strongly to call attention to them. The American climate, or climates (for there are many), have marked peculiarities, which, however, require only common-sense precautions to render them innocuous or even invigorating. Whenever a child thrives poorly, has chronic dyspepsia, and is pale and thin, a careful study of the clothing must be made. The underclothing throughout the year must be of wool, or of merino containing a large proportion of wool, the weight being of course adapted to the season. Slippers and low shoes must be eschewed, for the preservation of the warmth of the feet and legs is especially important.

Nothing is more valuable for children than to become accustomed to a daily sponge-bath with cool water, followed by brisk friction with a stout towel. This should begin not later than at the age of four years. The chill may at first be taken off by adding a little warm water, but it will soon become easy and pleasant to use it the year round of the temperature of the sleeping-room. Few children will become dyspeptic whose diet is reasonably wholesome and who chew their food properly, whose dress is suitable, and who are accustomed to the daily sponge-bath, with plenty of out-of-door exercise.

But when we are called to treat digestive disorders in children whose general health has suffered in consequence, it is, of course, necessary to use care in directing the proper kind and frequency of bathing. It may be necessary to restrict it at first to partial sponging with warm water, followed by general friction with a dry salted towel; but as soon as may be safe it is desirable to secure the tonic effect of the general cool sponging. In cases of more serious grade, where there is marked catarrh with great atony of the system, it is important to use daily inunction, with occasional sponge-baths with hot water and alcohol.

It is difficult to determine the proper amount of exercise for children, whether well or ailing. Their uncontrollable restlessness in health prompts them to as much as or more than is good for them. Not a few cases of dyspepsia result from indulgence in such constant activity as leaves too little nervous energy for vigorous digestion. Especially is this true of exercise soon after meals, which all observations show to retard this process. But in dyspepsia the child is often languid and indisposed to play or exercise; in which case it is essential to secure a proper amount of regular, gentle exercise, out of doors in fine weather and in-doors if inclement. Walking, riding a velocipede, horseback-riding, and light home gymnastics are specially recommended. The amount and kind of such exercise must be determined by the age, taste, and opportunities of the patient, and equally so by the influence upon the circulation, appetite, and sleep.

Abundant rest must be insisted upon. The child should retire early, and should always take a nap or a rest after the mid-day meal. In all cases where there is febrile action, and especially during the recurring spells of increasing irritation with vomiting and diarrhœa, the child must be kept in bed until his usual condition is fully regained.

It is impossible to discuss fully the details of the diet, but some general observations may be made. The meals must be regular, must be eaten slowly, and every mouthful must be thoroughly masticated. In cases of severe catarrhal type (chronic gastric or gastro-intestinal catarrh) and during the acute exacerbations of irritation which occur in many atonic cases, it is necessary to restrict food rigidly, and for the most part to liquids, until the vomiting and extreme gastric sensitiveness are allayed; after which a gradual return is to be made to the diet proper for the more chronic condition.

It is often necessary to allow considerable variety, as an insistence on monotony may breed disgust. But the variety should be only in the range allowed for successive days or weeks; at no one meal should strict simplicity be departed from. Thus it is always necessary to write out a bill of fare, stating the hours, articles, and amounts of each meal. Otherwise, with the best intentions on the part of the mother or nurse, the whims or persuasion of the child will insure imprudence. As a rule, food should be taken four times daily: occasionally it will be found that more thorough digestion is secured by limiting the meals to three, and not rarely it is necessary for longer or shorter periods to give food in smaller amounts and at shorter intervals.

It is necessary to determine whether the digestion of starchy foods is specially defective. This is the most common type of indigestion in children: so that, as a rule, the dietary should include very few farinaceous articles. This is, however, only a general rule, and there are many exceptions to it. In proportion as there are evidences of fermentation the above rule is valid. Then there are cases, and they probably constitute a large majority, which can be rapidly benefited by a diet chiefly composed of soft-boiled eggs; finely-minced lean meat; raw oysters; light broths; a little green vegetable, such as spinach, cauliflower, stewed celery, asparagus-tips, or raw tomato; and very little starchy food, and only in the form of soda-crackers, stale bread toasted, and rice; and for beverages, hot water and hot milk, separate or mixed; peptonized milk; milk containing Mellin's food; milk and lime-water, or rennet whey. Again, there are cases in which neither eggs nor milk can be taken, where the child wastes when restricted to meat and broths, and where it is found best to give at the morning and evening meals carefully-cooked (and, if necessary, peptonized) mush, and at dinner mealy potato either roasted or first boiled and then baked; together with stale bread-and-butter, which is most wholesome when the bread is cut thin and the small amount of butter is gently rubbed into it, instead of being smeared over it as is usual. The soft part of oysters, raw or broiled, fish, boiled or broiled, beef, mutton, chicken, game, are all well received in most cases. There is, indeed, rarely any difficulty in providing a sufficient variety of simple meals, each consisting of very few articles, if only the subject receives that share of attention which its importance demands.

Finally, it must be observed that the condition of the bowels and of the urine must always be considered in ordering the diet. Scanty and heavily-charged urine indicates deficient absorption of liquid (usually from a scanty supply of water) or excess of nitrogenized food, one or both. It is easy to aid in overcoming constipation, which is often troublesome, by modifying the diet; and, on the other hand, the appearance of loose, fermenting, and undigested stools must be met promptly by restriction and change of food.

The indications for the administration of medicine should be carefully studied so as to grasp the fundamental defect which gives its type to the individual case. Above all things is it essential to avoid the use of too much medicine, and to avoid altogether any prescription which disgusts the palate or disagrees with the stomach. The cure of catarrhal inflammation if present, the arrest of fermentation, the relief of vomiting, of hyperæsthesia, or of neuralgia, the restoration of tone to the gastric walls, and the improvement of the quantity and quality of the gastric secretions,—such are the prominent indications presented in various combinations and degrees in different cases. It may happen that the arrest of fermentation by the simple prescription of proper diet is followed rapidly by the subsidence of the dependent catarrh and by the disappearance of all symptoms of dyspepsia. But more often, unfortunately, if catarrhal irritation has been excited, it requires special treatment, in addition to all that judicious diet can effect; and not rarely this element dominates the entire management of the case.

Counter-irritation to the epigastrium, by repeated applications of mustard plaster or of iodine of proper strength, is then of decided value.

Nitrate of silver deserves the first place among the remedies for this condition. Its action is not limited to the gastric surface; it seems to act also upon the intestinal mucous membrane. It should be given in small doses; and in solution or in pill, according to the age or special indications of the case: usually the solution is to be preferred in cases of pure gastric trouble, the pill when it is desired to reach the intestine. Doubt is often expressed as to any possible value attaching to the use of minute doses of nitrate of silver (gr. $\frac{1}{12}$ to $\frac{1}{4}$ in adults; gr. $\frac{1}{48}$ to $\frac{1}{12}$ in children) in gastro-intestinal or duodeno-hepatic catarrh. The chemical nature of the remedy is soon changed; the amount is too small to act directly upon the extensive surface affected. But the condition present is one of such morbid irritability that a minute amount of any indigestible food—nay, in some cases, even a teaspoonful of distilled water—will cause distress, nausea, and vomiting. And it is entirely credible that the repeated administration of minute doses of this peculiar sedative astringent may, by means of widely-disseminated nervous impressions, induce positive therapeutic effects far beyond the area of its direct action. The argument of clinical experience is, however, conclusive: though it is proper to repeat the statement that tact and judgment are required to obtain from this remedy all that it is capable of yielding in these delicate cases.

Creasote is deservedly used much in catarrhal types of dyspepsia at all ages; for it has a powerful antifermentative effect, in addition to its valuable local action. Thus, it controls vomiting, lessens flatulence, and acts favorably on the irritated mucous membrane. It is, however, somewhat difficult to administer to young children, on account of its peculiar and unpleasant odor and taste. The following formula may be used:

℞ Sodii bicarbonatis, ʒi;
Creasoti (beech-wood), gtt. iv;
Pulv. acaciæ, q. s.;
Glycerinæ, fʒii;
Ol. cinnamomi, gtt. iv;
Aquæ puræ, q. s. ad f℥iii.
Ft. mist.
S.—A small teaspoonful in a little water soon after meals. For a child of six years.

Or the following:

℞ Creasoti (beech-wood), gtt. v;
Bismuth. subnitratis vel Sodii bicarbonatis, ʒi;
Pepsin. (saccharated), ʒi.
M. et div. in chart no. xxx. (in small capsules).
S.—One after meals. For a child of six or seven years.

Carbolic acid is less unpleasant in odor and taste, but it is also less efficient for this purpose.

It is, of course, to be understood that what is now said is to be regarded as merely supplementary, as regards older children, to the remarks already made upon the treatment of habitual indigestion in infants.

Sulphurous acid is occasionally very valuable, even when vomiting is a prominent symptom; but it is especially indicated where there is gastric atony with flatulence, with discharges of ill-smelling flatus:

℞ Acid. sulphurosi, gtt. xvi;
Aquæ cinnamomi, f℥iv.
M. S.—From twenty to sixty drops in a dessertspoonful of water, according to effect, three or four times daily.

To this mixture it is often desirable to add one-fourth of a grain of strychnine; or the following may be substituted:

℞ Quininæ sulph., gr. xxxii;
Strychninæ, gr. $\frac{1}{4}$;
Acidi nitromuriatici diluti, fʒi, vel Acidi phosphorici dil., fʒii;
Tinct. cardamomi comp., fʒii;
Aquæ puræ, q. s. ad f℥iv.
Ft. sol.
S.—From thirty to sixty drops in water after meals. For a child of from seven to ten years.

Pepsin, in some one of the highly-acceptable and reliable preparations now available, is an important aid in the treatment of many cases where the gastric secretions are deficient in quantity or quality, or in both.

When the stomach is settled, and reasonable amounts of food can be taken, the depravation of general health may suggest the use of cod-liver oil; and it is under such circumstances often taken willingly and with admirable results, pure, or in jelly, or in the form of an emulsion with lime (see page 15), with hypophosphites, or with wild-cherry bark:

℞ Ol. jec. aselli, f℥iss;
Pulv. acaciæ,
Sacchari, āā, q. s.;
Ext. pruni Virgin. fluid., fʒiii;
Aquæ puræ, q. s. ad f℥iv.
M. et ft. emuls. sec. art.
S.—From one to two teaspoonfuls after meals.

What was said on page 16 in regard to the use of arsenic and iron might be repeated here.

The use of stimulants in the chronic dyspepsias of older children should be directed with caution and hesitation. Very often in severe cases small amounts are required for short periods, on account of weakness and depression: their beneficial action is shown by improvement in appetite, in the appearance of the tongue, and in the circulation. In some cases of obstinate vomiting, spoonful doses of iced champagne, or of carbonic-acid-water containing a few drops of brandy, may succeed when many efforts have failed to arrest it. But there is much to be said against the prolonged use of stimulants, because of the loss of effect which follows, and of the risk of increased local irritation, and, in the case of older children, on account of the moral question involved. No such objection applies to preparations of malt, of which there are excellent ones in the market, and which often prove highly useful in these cases, by improving appetite, digestion, and nutrition.

Allusion must be made to the constipation which attends some cases and may be very troublesome. In each case the special cause of the constipation should be determined. If due to relaxation of the abdominal and intestinal muscles, owing to atony and flatulent distention, it may be relieved by friction, massage, and electricity, added to the cool sponge-bath. If owing to scanty intestinal secretions, modifications of diet, increased supply of water, the omission of all astringent remedies and the use of those which, like arsenic, the mineral acids, and nux vomica or strychnine, stimulate secretion and peristalsis, may suffice to overcome it. In either case the use of suppositories of gluten or glycerin or occasional enemas will give important aid if required. Laxatives, even of the mildest kinds, are to be avoided as far as possible. Most of them lessen appetite and impair digestion, and their action is apt to be followed by a reaction of greater torpidity. Occasionally, however, in spite of such measures, there is such severe constipation as to demand special medication. Small amounts of Carlsbad salt in hot water may act gently and kindly. Elixir of cascara may be given in carefully-graduated doses, or the solid extract in pill form if the child be old enough to swallow a pill. If iron is indicated in the same case, some such combination may be used as—

℞ Pil. ferri carb., gr. xvi;
Ext. cascaræ, gr. viii;
Ext. nucis vomicæ, gr. ii.
M. et ft. mas. et div. in pil. xxxii.

S.—One, two, or three daily after meals as required. For a child of from seven to ten years.

Or

℞ Ferri sulph. exsiccat., gr. x;
Pil. alöes et myrrhæ, gr. xvi;
Ext. taraxaci, gr. xvi.
M. et ft. mas. et div. in pil. xxxii.
S.—One twice or thrice daily after meals.

In all cases it is proper to begin cautiously with small doses, as the object is to produce not only a laxative but also a tonic action, so as to promote a regular habit of the bowels. Any overaction is to be deprecated; and, as already stated, laxatives are to be used only when it is impossible to get along without them.

CYCLICAL, FITFUL, OR RECURRENT VOMITING.

This condition, which is, we believe, by no means so rare as has been thought, has received comparatively little attention from medical writers in the past, and in consequence a large part of what we have to say comes from our own experience. Gee, of London,[1] has recorded no fewer than nine cases, all of which are particularly interesting.

Definition.—The state is one characterized by attacks of vomiting which recur after intervals of uncertain length, and between which the person is apparently in the enjoyment of perfect health. Generally the attack lasts but a few hours, but it may extend over three or four days, in which case the condition of the patient may approach that of profound exhaustion. The disorder occurs at all ages, and I have met with it at the various periods of childhood quite as frequently as in adults.

Symptoms.—Very commonly the attack is preceded, and it is nearly always accompanied, by pain in the upper part of the belly or around the navel, which in some cases is so severe as to require, for the time-being, more of the attention of the physician than the vomiting. The bowels are generally costive, but in a large number of cases they are loose or unaffected, and it is worthy of note that in every instance the stools are of a lighter color than normal. This condition may persist for some weeks, or even months, after the attack; and it appears that while the stools show such want of bile the tendency to recurrence of the attacks continues.

The vomiting differs in no way from that commonly seen in children, save in its periodicity of occurrence, the ejecta being made up of the gastric contents, and perhaps bile; towards the last it may be only watery, or it may contain traces of mucus. The violence of the gastric disturbance differs in different cases. In some the attacks consist in a refusal on the part of the stomach to receive any liquids or solids; in others the retching and straining keep on whether food is taken or not; while in still others it happens that the gastric irritability shows its presence at certain periods of the day only, food being retained at other times. In cases where the attacks are prolonged for several days, and the vomiting is severe, the amount of depression resulting may seem highly alarming and dangerous. After the attack has passed away the walls of the abdomen are often tender and ache, from the efforts at vomiting.

---

[1] St. Bartholomew's Hospital Reports, 1882, vol. xviii. p. 1.

In some of the cases fever of an irregular type may accompany the gastric disturbances, while in others no variation of temperature occurs. In one of Gee's cases, where the vomiting was replaced by retching without the expulsion of the contents of the stomach, the attacks generally lasted but for a few minutes, were accompanied by no pain, but by marked pallor of the face, and the temperature of the body at certain times rose as high as 105° F. without any obvious cause.

Etiology.—It has seemed to me that the essential element in the production of recurrent vomiting is a state of nervous depression and irritation affecting especially the centres and fibres supplying and controlling the stomach and liver. I have known this condition to be established almost immediately by a nervous shock, or by excessive fatigue, though more usually it is brought on by the prolonged action of depressing causes. When once it is established, it requires comparatively slight influences to excite a spell. The symptoms indicate the existence of hepatic torpor in most cases, and not rarely a slight degree of gastric catarrh is associated. Not improbably it is the development of some irritating ptomaine which causes the explosion; or else it is a lowering of the already depressed innervation which violently disturbs the equilibrium of the gastro-hepatic functions. Indigestible food is not so common a cause as might be expected, unless articles difficult of assimilation are taken at about the time that an attack is likely to come on. In many cases exposure to cold seems to be the provoking factor, while in other cases the closest observation may fail to discover anything which can be called a cause. The truth is that the underlying tendency above alluded to, however acquired, varies greatly in its intensity in different cases, so that the causes needed to call it into action vary greatly in degree, and vary also in kind, according to the different susceptibilities of the individuals affected.

The periodicity of the attacks is difficult of explanation. In some instances the spells recur at such irregular intervals as scarcely to merit the name of cyclical: they show only the existence of a continuous tendency which is aroused from time to time by the recurrence of the exciting causes. In other cases greater regularity in recurrence is noted, suggesting that the susceptibility of the nervous system is developed periodically under the operation of some rhythmic influence. It may be that these attacks of a more strictly cyclical character are sometimes the evidence of a gastric *petit mal;*

and even when this cannot be established, there are interesting and important analogies suggested. Rarely malarial poisoning may be at the bottom of the disease, and under such circumstances the attacks are apt to be peculiarly regular in their recurrence.

Occasionally the development of the condition may clearly depend upon a preceding acute disease. Thus, I have seen it follow typhoid fever; and in one of Gee's cases no other cause could be assigned than an attack of measles occurring twelve months previously. In this case the attacks of vomiting were very frequent, recurring as often as once a week.

Treatment.—It is evident that one of the first things to be done is to prevent exposure to the exciting cause in each instance, and so to regulate the diet and the functions of the digestive canal as to prevent the production of catarrhal states, or the development of the poisonous matters which are formed by the fermentation of food in the stomach. The vomiting, if severe, should be treated by doses of calomel and bismuth, or, if such medication fails, bromide of potassium, or chloral, or small doses of laudanum, should be administered in weak solution by the rectum. As the vomiting goes on, there is frequently a tendency to collapse; and it is in this stage that brandy in a concentrated form, and preferably hot, seems to act with particularly good results, producing a stimulation of the flagging nervous power and allaying the tendency to vomit. Here, again, medication may be by the bowel if the stomach refuses to receive any liquid, the brandy or whiskey being warmed thoroughly, and in this case diluted sufficiently to avoid rectal irritation and tenesmus. For the abdominal pain, which is, as we have stated, often severe, external applications only should be employed, such as very weak mustard plasters containing just enough of the mustard to bring a blush to the skin over the epigastrium. The hot brandy often brings relief in this state also, and the well-known spice plaster, made up of allspice, cloves, cinnamon, and black pepper, is often a remarkably good application. Opium should be avoided as far as possible, as, although its use brings temporary relief, it may be followed by so much systemic depression as to do more harm than good. Not only is this true, but, by the locking up of the undigested food in the bowel, fermentation is increased and true gastric and intestinal catarrh may result. Not rarely, however, after the stomach and duodenum have been emptied by repeated acts of vomiting, and when the bowels have been moved spontaneously or by the aid of an enema, and when the retching and straining continue frequent and severe, it is necessary to administer small doses of opium by the rectum. I have had some highly interesting results from the use of small doses of antipyrin administered in cyclical vomiting as soon as the first symptoms of an attack present themselves. These results encourage a further use of this remedy in such cases.

If collapse is threatened, hot applications and cardiac stimulants are strongly indicated, and should be pushed until some reaction sets in.

Where the exhaustion is due to the inability of the child to retain food rather than to excessive retching and abdominal effort, nourishment should be given by the rectum in the form of predigested milk, such as is now so readily prepared by means of the pancreatic preparations.

GASTRALGIA.

Synonymes.—French, Gastralgie, Gastrodynie, Cardialgie; German, Magenschmerz, Magenkrampf; Latin, Erethismus ventriculi, Hyperæsthesia ventriculi; English, Spasm of the stomach, Nervous cardialgia, Gastrodynia.

This affection is rare in children; yet, as it occurs, it merits attention.

Definition.—An affection characterized by sudden, sharp, lancinating pain in the stomach, coming on without premonition, as a general rule, and lasting for a few moments or, in rare cases, a number of hours. It is distinctly a neurosis, and, while the sensation experienced by the patient may be that of gastric spasm, it is probable that no real contraction of muscular fibre occurs.

There is no organic lesion of the stomach associated with the trouble, nor is there any marked functional disturbance. It is to be clearly separated from the pain accompanying either one of these states, and is in reality a violent form of neuralgia affecting nerves so closely associated with vitality as to cause more distress and fear than similar affections elsewhere. It is true that in some forms of dyspepsia the amount of epigastric distress or actual pain may be so great as to form the most prominent symptom in the case; but it should be clearly understood that even such cases cannot with accuracy be styled gastralgia.

History.—In the past there has been much confusion regarding this disease, and in consequence various terms have been used to indicate it which have in reality no appropriateness and in many instances are so out of place as to express affections of other organs than the stomach. Thus, even at the present time the terms cardialgia, gastrodynia, spasm of the stomach, stomachic colic, and neuralgia of the stomach are all used to signify one and the same disease. It is evident that the first of these is an absolute misnomer, while several others are expressive of quite another state than that which exists. The only terms which may correctly be used as synonymous are gastrodynia and neuralgia of the stomach.

As already stated, gastralgia is comparatively rare in children, seldom being seen below fifteen years of age, and in this matter it agrees with our experience in respect to other forms of neuralgia.

Etiology.—The causes which induce gastralgia are various. Sex is a strong predisposing cause, and, in consequence, girls are much more commonly affected than boys. This is particularly noticeable at the approach of puberty. Temperament is even more potent than sex, since neurotic children suffer more frequently than those of a phlegmatic type. Again, that great and potent cause of neuralgia, improper nutrition, with its invariable concomitants, anæmia and debility, also is found to be here present as an exciting cause. Depressed vitality, nervous strain, excessive excitement, privations, exposure to cold, and sudden fright and grief are all causes. The ingestion of exceedingly cold liquids or solids and the sudden suppression of old and chronic cutaneous discharges have been long recognized as factors in the production of gastralgia; while the migration of parasites from the intestine into the stomach is probably a more common factor than is generally assumed.

The question as to how frequently the ingestion of indigestible foods is a cause is an exceedingly difficult one to answer, owing to the frequency with which pain follows such acts even under ordinary circumstances; but in the vast majority of cases true gastralgia is not so produced.

It is, however, evident that when the neuralgic tendency exists the irritation caused by the presence of indigestible food may readily excite a paroxysm. These are the ordinary causes in children, but attacks of pain altogether resembling gastralgia may be caused by organic disease in other parts. Thus, incipient caries of the dorsal vertebræ may, by irritating certain nerve-filaments, cause such spells of pain.

Certain cases are but the manifestation of malarial poisoning, and Niemeyer has pointed out that attacks of gastralgia are sometimes present in lieu of a chill. Rheumatism may perhaps be a cause, but, unless the hereditary tendency is most striking, it seldom can be looked upon as such in children.

The habit, so prevalent in the lower classes, of permitting the use of coffee and tea by very young children is undoubtedly an occasional cause of this rare disease, as it often is in adults. In boys who begin the use of tobacco before puberty this drug has a powerful predisposing influence, and Stillé believes that this is the most common cause of gastralgia in adult males in the United States.

Pathology.—Numerous views have been brought forward to explain this interesting disorder. It is supposed that the nerves involved are the sensory fibres of the pneumogastric and the solar plexus, and in all probability it is the former which are most commonly at fault. The nerve-supply of the stomach is very closely connected with that of the general abdominal cavity, for the right vagal branches are distributed to the posterior surface of the stomach, after which they join the left side of the cœliac plexus and the splenic plexus. The left vagal branches are distributed over the anterior surface of the stomach and to the lesser curvature. They unite with the branches of the right vagus and with the sympathetic, and some filaments pass through the lesser omentum to the left hepatic plexus. For these reasons it is readily seen that very widely separated causes of irritation may produce the trouble, and also how readily the abdominal contents, as well as those of the thorax, might share in a paroxysm of pain. It has been already pointed out that this disease is to be separated from the pain accompanying gastric troubles, organic and functional.

Symptoms.—The symptoms of this disease are easily recognized. The child, without apparent cause, is of a sudden seized with a pang which in its severity is to be compared to that of angina pectoris, the face becomes pinched and livid, and the belly-walls are found to be retracted and knotty, or relaxed from the depression of excessive pain. At the onset of the paroxysm a sharp cry is given, and the hands may be pressed against the epigastrium while the body is bent over in agony. The pulse is slow and full, owing to the involvement of the filaments of the pneumogastric, or in other cases is equally rapid and running, but is always hard. The sensation on applying the finger to the pulse in the wrist is one of high arterial tension in the early stages of the trouble, and remains so through the attack, unless the paroxysm lasts an unusually long time, when the exhaustion of prolonged suffering may relax the spasm of the blood-vessels as it is apt to relax the entire body.

If the attack is one of a fleeting character, a single dart of excruciating agony may cause the child to give one loud scream and to fall to the ground in the acme of its pain. The skin may be covered with sweat at the height of the paroxysm.

It is of importance to remember that children very frequently find difficulty in referring to the seat of pain, be the pain where it may, so that heart-pains are often referred to the abdomen, and abdominal pain to the chest. In some cases the pain has its onset only when the stomach becomes empty, or in still others vomiting may occur.

Sometimes the attacks are periodical. In these cases there is a sensation of fulness in the stomach even amounting to a feeling of bursting, and epigastric pressure may or may not be accompanied by relief. In the cases where the sensation of fulness is felt, the application of pressure is often disagreeable or even painful. Pulsation in the epigastrium is sometimes seen, and in rare instances the pain extends to other parts of the body, so that the chest and even the arms may suffer in the general nervous storm. If any hysterical tendencies exist, there are often shortness of breath and irregularity of the heart's action preceding the attack, associated with those general symptoms so commonly seen in hysteria. Here, as in all forms of irregular hysterical manifestations, the differential points as to the cause of the trouble may be sought after without finding a ready explanation.

Diagnosis.—The diagnosis of gastralgia from other painful affections of the stomach is of great importance.

Gastric cancer, which in children is of extreme rarity, can scarcely be mistaken for it. The pain is more apt to follow the ingestion of food, while in gastralgia it rather occurs shortly before the time of meals; vomiting is common; palpation detects a sense of induration or a distinct tumor, and cachexia soon makes its appearance and can be distinguished readily from the anæmia or even the chlorosis which may attend gastralgia.

Again, the acute, sudden, fleeting form of gastralgia may resemble a *petit mal*, somewhat, when it is epigastric. The separation of these two diseases is vitally important for prognosis and treatment, and is by no means readily accomplished, save as the case progresses. Although *petit mal* is not so rare as gastralgia in children, this particular form of pain in the belly as a symptom of the state of minor epilepsy is quite as rare, if not more so; indeed, we have known of only one such case, which afterwards passed into major epilepsy and died. In this instance the child would suddenly cease its play, give a scream of pain, and return to its toys.

While the immediate diagnosis between the two affections may be difficult, the past and the subsequent history of the case separate the facts into lines which point more and more divergingly to epilepsy or gastralgia.

The disease most closely resembled by gastralgia is, after all, gastric ulcer, but the latter is so rare in children, and is so generally associated with other signs when it does occur, that it can be excluded in making a diagnosis. There are usually also progressive wasting, an habitual rejection of food, a more frequent onset of pain after food, and more evidence of functional gastric disturbance in gastric ulcer than in gastralgia. The pain in ulcer is also more circumscribed, and the matters vomited may contain more or less blood.

From intercostal neuralgia it is to be separated by its location in the epigastrium; by the fact that the pain appears less superficial; by the absence, except in rare and unusually severe cases, of pain in the chest increased by respiration; and by the absence of painful nerve-points or hyperæsthesia along the course of a superficial nerve, as may be found in pleurodynia.

Gastralgia and hepatic colic may occur with symptoms nearly allied, but the icterus, the prolongation of the pain for a certain length of time, the tenderness over the hypochondrium, and the history of previous attacks of biliary colic will establish the diagnosis. The fact that one of the vagal branches is distributed to the hepatic plexus may make the differentiation, so far as the area of the pain is concerned, impossible.

From the pain of functional gastric disorders gastralgia is divided by the suddenness of its onset, by the lack of eructations and vomiting, and by the absence of a coated tongue and of tumidity and tenderness of the belly.

Cardiac disease may directly or indirectly produce symptoms of gastralgia. Either the pain may be referred by the patient to the abdomen, as we have said, or it may in reality exist there by reflex action or disordered circulation.

Treatment.—The treatment of gastralgia may be divided into two parts,—that directed to the relief of the attack when it is present, and that directed to the prevention of other attacks. During the acute stage hot applications and drinks, aromatic and locally stimulating warm infusions, a few drops of chloroform, or brandy, or whiskey, hot and concentrated, or a few drops of laudanum, may be used. Counter-irritation often does good, and in some cases, particularly if a suspicion of an hysterical element exists, a vigorous revulsive may act with surprising power. Emesis and purgation are sometimes indicated, since in the early attacks the cause of the pain may be suspected to be the presence of indigestible food.

The treatment required in the intervals between the attacks must vary with the cause and with the general condition of health. A careful search must be made for the real cause of the trouble, and when found it must be removed or palliated by appropriate measures.

The diet should be carefully regulated, and all the hygienic details of the child's life be critically studied and directed. The avoidance of improper food, the abandonment of tea, coffee, or tobacco, the prescription of proper dress, exercise, or change of residence, may be followed by marked improvement in general health and by a cessation of the attacks of gastralgia.

In regard to remedies, it may be premised that all depressing drugs must be avoided, as well as all purgatives which would weaken the digestion. Any marked disturbance of digestion should be corrected; and this may require the use of pepsin, or of some tonic remedies such as suggested in the article on dyspepsia. The chief reliance is, however, to be placed upon the administration of arsenic and iron immediately after meals, in proper form and doses. Thus, we may direct—

℞ Liq. potassæ arsenitis, fʒi;
Vini ferri amari, q. s. ad f℥iv.
Misce.

S.—From thirty to sixty minims in water after meals three times daily, for a child of six years.

Or

℞ Tinct. ferri chloridi, f℥i;
Acidi muriatici diluti,
Liq. arsenici chloridi, aā, f℥ss.
Misce.

S.—From four to eight drops in water after meals three times daily.

Occasionally even better results are secured by the use of cod-liver oil in emulsion with hypophosphites. It is well, in cases where the tendency to pain is decided, to combine with the above the use of a powder of bismuth subnitrate and saccharated pepsin, given about an hour or an hour and a half after meals. Constipation, should it exist, may be overcome by diet, massage, enemas, or by suppositories of gluten or glycerin and soap. If the bismuth favors its continuance too decidedly, small doses of cyanide of potassium, dilute hydrocyanic acid, or chloroform may be substituted at the same hours. In cases where a highly neurotic state exists, it may be necessary to alternate with the bromides or preparations of valerian.

DISEASES OF THE STOMACH.

By HOBART AMORY HARE, M.D.

While it is true that during the period of childhood the stomach is the organ most frequently at fault, careful thought will show very clearly that in nearly every instance the symptoms surround a gastric condition of perverted functional activity, and not one of essential morbid change. For this reason our knowledge of gastric disease occurring before puberty cannot be aided by post-mortem research in those cases which go on to a fatal termination. In the adult, on the contrary, trouble with the stomach is commonly dependent upon actual morbid changes, which in some cases are characteristic of certain periods of life, and in others may be regarded as the results of the prolonged continuation of functional disorder. In the child functional disturbance is generally so mild that the youthful tissues repair any injuries, or else is so severe that death ensues before any structural alterations can occur. Further than this, the natural course of events prevents, to a large extent, any abuse of the stomach sufficient in severity to bring about in children gastric ulcer and similar states, and even if the same causes are at work their manifestations are so positive that their existence is recognized, or forced upon the parents, by the violence of the systemic symptoms,—symptoms which in the adult are hidden by a greater degree of vital resistance and stability, or else are purposely and persistently ignored, until such advanced changes take place that ineradicable structural alterations are developed.

For these reasons, it has been thought well to separate the consideration of gastric disease into two parts, the first of which, by Dr. Pepper, deals with those disturbances of function which are more commonly seen in children and which arise from errors in diet and other similar causes, while the second part deals with gastric disorders accompanied by distinct organic change, readily demonstrated by a macroscopic or a microscopic examination, and equally characteristic in all cases.

The functional disorders are more frequently seen and more readily cured, while the diseases associated with distinct lesions not only present for treatment many of the signs seen in the previous class, but also force the physician to the care of altered tissue. For these reasons the subject of *diseases* of the stomach lacks the importance in children which it possesses in adults.

No better example of this can be found than the subject of gastric ulcer. Careful search through the literature of medicine shows so few cases of true ulcer of the stomach in children as to make it evident that this very common ailment in adults is a curiosity before puberty, and also shows that only one or two of the cases on record present signs of ulcer distinctly comparable to the lesion as found in the adult. Without entering into a useless discussion concerning the etiology of such a state, logical deduction and the reports of the instances where the disease has been seen in childhood show that the causes at this period of life are inevitably different in character and mode of action. The majority of instances of gastric ulcer in children have been found complicating and due to general tuberculosis, and have been multiple and distributed widely, not only over the gastric walls, but also far into the duodenum and even up into the œsophagus. In other words, the gastric affection is only a small part of the trouble present, and exists not as a well-defined, localized lesion as seen in the adult, but as a fractional part of a wide systemic involvement of almost every part of the body. Gastric ulcer in the adult is a local malady, while gastric ulcer in the child is in most cases only a part of a constitutional disease. As a natural consequence, we find that the treatment of ulcer of the stomach in the child is separated from that of the disease in the adult, for, if the trouble be constitutional rather than local, therapeutic measures must be addressed quite as much to the improvement of the general system as to the local lesion resulting therefrom.

By far the most important fact to be remembered in the diagnosis and treatment of gastric disease in childhood is that symptoms pointing to other regions than the stomach may be present in such force as to cover completely the true source of the malady. In the following pages I have pointed out the fact that children commonly refer pain and discomfort to portions of the body which we know, by their anatomical position, cannot be involved even sympathetically with the stomach. Not only is this the case, but, in addition, it is to be remembered that disease of other parts may be produced by such troubles. A child, after slight fatigue and no known change of diet, is taken ill with what seems to be a severe coryza: the nasal mucous membrane streams with mucus, and the eyes are somewhat injected and tearful. After a few hours a loose cough is developed which is frequently repeated and harassing, and pain in the throat is complained of. Restlessness at night becomes a pressing symptom, and careful examination by the hand shows epigastric tenderness. The tongue is coated unevenly and is flabby. Careful questioning develops the fact that the child had been restless at night for a week before any other signs appeared, that the appetite has been getting progressively worse, and that the bowels have been confined. Pain in the stomach from flatus has also been present.

Here are all the signs, at the early stage, of what is commonly called "a cold," but which are produced reflexly by the condition of the stomach. In some cases the "cold" may be "caught" owing to exposure when the system is depressed; but, be this as it may, measures directed to the air-passages are useless until the gastric condition is set right. Expectorants, tonics, and all else fail if the stomach is neglected.

The use of such drugs very commonly seems to aggravate the symptoms. Quinine may be given to relieve a state of listlessness supposably due to debility, and only serve to irritate the gastric mucous membrane the more. Nearly all tonics in the early stages of gastric inflammation do likewise, for at this time the inflammation causes an excessive activity of the cells. Only in the later stages are tonics to be given to do what their name implies,—add tone to the part.

In all cases of disease in children the physician should carefully examine into the condition of the stomach before the administration of drugs is begun.

GASTRITIS.

Synonymes.—Inflammation of the stomach, Gastric catarrh, Inflammatory dyspepsia; French, Embarras gastrique; German, Magenentzündung; Latin, Inflammatio ventriculi.

Definition.—As gastritis of an idiopathic type rarely, if ever, in children involves more than the mucous membrane of the stomach, seldom dipping down into the submucous and muscular coats, I have preferred to divide the consideration of this subject into two separate parts, under the headings of acute gastric catarrh and chronic gastric catarrh, descriptions of which here follow.

There may be, however, a deep-seated gastritis produced by the ingestion of irritant matters of various kinds, and perhaps no better opportunity for its consideration can be found than at this place.

In all cases where acids and alkalies of a strong and irritant character are swallowed, intense general inflammation naturally occurs; and this is true in very young children if any of the irritant spices, such as pepper, for example, are taken in excess. Sometimes a similar state is induced by the accidental swallowing of hot liquids, which, after injuring the œsophagus, injure the stomach. In these cases the inflammation is distinctly of a traumatic origin and can be clearly separated from the idiopathic forms, which have no such history. Blows upon the epigastrium may cause gastritis.

The symptoms are intense epigastric pains, vomiting, and sometimes a raised or lowered bodily temperature. The belly, at first scaphoid, rapidly becomes tumefied, and if the inflammation is very severe the case goes on into general involvement of the peritoneum and intestines by extension of the inflammation. After death the mucous membrane is intensely engorged, reddened, and angry-looking. The lymph-glands of the submucous coat are raised above the surface and hardened. Mucus in large amount, perhaps tinged with blood, is seen spread over the inflamed surface in patches. All the coats are infiltrated with lymph, so that the walls of the organ are much thickened. The muscular layers are found to be swollen, and evidences of their paralysis by inflammation may be recognized by the retention of food in the viscus.

The *treatment* is to be directed entirely to the prevention of the spread of the inflammation and to the relief of that already developed. If the patient is seen soon after the onset of the trouble, the stomach is to be emptied of all irritant substances by means of vomiting induced by large draughts of warm water, or by the use of the stomach-pump. Mucilaginous drinks are to be given freely, and albuminous matters seem especially useful. Oils and similar protective liquids aid in preventing further damage. Opium, to allay pain and the local and systemic irritation, is invaluable. It should always be given in liquid form, and the deodorized tincture is the best in this respect, owing to its freedom from narcotine. Paregoric contains too little opium, and is irritating because of its volatile oil. If the stomach will bear no drugs, they should be given by the rectum. If evidences of collapse appear, hot applications, atropine, or belladonna should be exhibited. It is important that the heat should be applied over the epigastrium and chest, and a flaxseed poultice is the best method of doing this.

The after-treatment must be directed to the support of the patient, the avoidance of all exposure for a long period of time, and the use of foods which are entirely devoid of irritant matters and easily digested.

DIPHTHERITIC GASTRITIS (Teriche[1]) is a lesion so completely secondary as to be worthy of only passing mention. As its name implies, it is caused simply by an extension of the false membrane down the pharynx and the œsophagus until the stomach is reached. It is exceedingly rare. Niemeyer[2] states that in infants the catarrhal inflammation sometimes goes on into the croupous.

ACUTE GASTRIC CATARRH.

Synonymes.—Status gastricus, Gastricismus, Gastrosis, Disordered stomach.

Definition.—A disease characterized by vomiting preceded by listlessness, anorexia, and nausea. In the older child the refusal of food may be absolute, but in the infant the breast may at first be taken eagerly, the milk being almost immediately ejected. It is, particularly in its milder forms, a very common ailment in children. Pathologically it consists in a hyperæmic condition of the gastric mucous membrane, and, as a consequence of this, there are increased secretion from the mucous glands and a diminished flow of gastric juice, according to the belief of many well-known authors, although, so far as we know, there is no reason for believing this condition to be present other than that digestion is impaired. The lesions found, if death occurs, may be so slight as to be out of all proportion to the intensity of the digestive disturbance during life. Occasionally the hyperæmia of the living stomach is lost in the anæmia of the organ in death. Descroizilles[1] asserts that the mucous glands are enlarged so as to form many inequalities over the membrane, and in this he would appear to be in accord with Widerhofer[2] and Kundrat, who believe that there must be some abnormal change in these bodies.

---

[1] Ziemssen's Cyclopædia, vol. vii.

[2] Practical Medicine, vol. i. p. 503.

Etiology.—The causes of this affection are exceedingly varied, but the chief of them depend upon badly-prepared or indigestible food, or, if the food is not really indigestible, upon some condition of the digestive function which renders even the ordinary liquids obnoxious to the gastric mucous membrane. Very commonly do we see, in bottle-fed infants especially, attacks of indigestion and mild or severe gastric catarrh produced in some inexplicable manner, even though the food has been prepared with the greatest care and has agreed with the stomach for weeks or months. Eustace Smith asserts that a cold is a very frequent cause of the disease, producing a hyperæmia of the gastric mucous membrane rather than of the mucus membrane of the pharynx. In his experience exposure to cold is a more frequent factor than anything else, and there can be no doubt that repeated exposures followed by acute gastric catarrh are powerful predisposing factors in the development of subsequent attacks. Improper clothing, by exposing the child's abdomen and epigastrium to draughts of air or to damp and cool air, renders the patient peculiarly susceptible. We are inclined to think, however, that exposure is in America a much less frequent cause than bad feeding, and that poor or improperly-prepared food is the chief factor.

Breast-fed infants rarely suffer from it, and, when they do, change in the maternal system, or cold, is the common cause. Dentition is undoubtedly a common exciting cause, as is also general vital depression and enfeeblement, particularly in the lower classes, who are surrounded by poor hygienic conditions.

There are other causes of a more constitutional character than those just mentioned, which may act as factors. In rickets there is nearly always a marked susceptibility to catarrh, and, as might be expected, scrofulosis is not an infrequent agency. In some cases there seems to be a strong predisposition to gastric catarrh which may appear to be hereditary.

Irritant substances swallowed by mistake or given by the physician may produce this condition, notably the use of ipecac in full dose, or the employment of the various so-called peripheral emetics possessing local influence, as tartar emetic and sulphate of copper, or mustard-water.

In children who are old enough to take "table-food," as it is generally called, there are several causes of acute gastric catarrh which are frequently overlooked. There can be no doubt that the ingestion of hot coffee and tea is a common cause, the heat doing as much damage as the drugs themselves. Not only is this statement based on general clinical evidence, but it is supported by experimental facts. Thus, Decker,[1] of Würzburg, has found it possible to produce even gastric ulcer in dogs by feeding them by means of a stomach-tube on food heated to 120° F. (49° C.); and the well-known fact that adults, particularly females, who drink large amounts of hot tea are subject to a similar disorder (gastric ulcer) is additional evidence. Alcoholic beverages are also productive of gastric catarrh, and, while the majority of children do not indulge in such liquids, the infantile members of most German families emulate their parents in the consumption of beer to an astonishing degree.

---

[1] Manuel de Pathologie et Clinique des Enfants, Paris, 1883.

[2] Gerhardt, Handbuch der Kinderkrankheiten, Bd. iv., Tübingen, 1878.

Secondarily, acute gastric catarrh may occur in the course of the fevers, as in pneumonia, typhoid fever, and erysipelas; and, lastly, tuberculosis, syphilis, and renal disorders may predispose to, or produce, such an inflammation. Once set up, the disease aids itself by the mucus secreted, which undergoes fermentation and consequently irritates the stomach still more.

Anæmia is productive of gastric catarrh in a twofold manner,—primarily by lowering the resistive tone of the gastric mucous membrane, secondarily by the lack of digestive power which is sure to accompany it. We see these facts illustrated almost daily in adults, and it is fair to assume that in both the full-grown individual and the child the digestive juices are under such conditions much impaired as to both quantity and quality. For this reason small and delicate children are particularly apt to suffer from this very malady. Aside from these points of clinical evidence, we are possessed of direct experimental proof of our deductions, for Manassein[2] has shown that after artificial anæmia is caused in dogs the normal relation between the acid and the pepsin of the gastric juice is destroyed.

It is disorder of the digestive juices which brings on gastric catarrh, since by this means food remains too long in the stomach and ferments. As the digestive juices have been found to be altered in animals and men suffering from fever, it would appear probable that the gastric catarrhs of febrile states are thus produced. In those cases where stomatitis exists it is exceedingly common for the patches to go down into the stomach, producing gastric catarrh and intestinal disturbances.

Pathological Anatomy.—We have already described with sufficient clearness the state of the stomach after death. The lining membrane of the stomach is often covered completely by a layer of tough tenacious mucus, and the hyperæmia is frequently hidden by this means.

Symptoms.—There are two distinct types of this disease, so far as disturbances of the bodily temperature are concerned. In one type the temperature remains about normal, in the other there is often pyrexia; but we think that the former is the more common of the two unless the irritation is extreme or the trouble depends on strumous or tubercular taint.

---

[1] British Medical Journal, 1887.

[2] Virchow's Archiv, lv. 451; also Centralbl. f. d. Med. Wiss., 1871, p. 853.

The first is shorter in its duration than the second, and is, as one would naturally suppose, far less serious. The extremities are often cold and perhaps moist.

Early in the disorder there may be anorexia, and listlessness amounting almost to relaxation. The eye loses its lustre, and drowsiness, which does not deepen into sleep, asserts itself. Nausea now comes on, and, if the child is old enough, headache of a more or less severe type is complained of. Vomiting soon replaces the nausea, and at first consists of the contents of the stomach, which are sour and ill-smelling. If milk has been taken, it is always curdled. The vomiting does not cease with the expulsion of the food in the stomach, but continues until mucus and perhaps bile make their appearance. If the vomiting is a late symptom the mucus may coat the food in the form in which it was swallowed, acting in such a way that the digestive fluids cannot attack it. Retching now supervenes, and may be painful from its severity as well as exhausting, and at the same time, or commonly much earlier in the attack, the tongue becomes coated and whitened, save at the tip and edges, where it is red and glazed. The papillæ of the tongue are prominent and project above the coating, dotting the organ with red spots.

This condition may persist for a varying length of time, but eventually ends by slow return to normal digestive and general power, or more rarely the return to health is rapid. Commonly other areas of mucous membrane suffer, so that coryza or mucous purging may be present.

If the attacks are frequent they speedily influence the general health.

There is sometimes epigastric tenderness, but this is rarely marked.

There are other evidences of disorder of the gastric mucous membrane than the localized stomach-symptoms and the prostration which have been spoken of. The surrounding organs become disturbed, particularly the small intestine. As a consequence the case may become one of gastro-enteritis, or more rarely icterus and constipation ensue. The breath is, from the first, foul and heavy, while the secretion of saliva may be abnormal in quantity, sometimes dribbling from the mouth. The urine is often scanty. If the systemic disturbance is great, herpetic blisters appear about the mouth, in children who are subject to such symptoms.

In some cases the symptoms become far more severe than any we have yet mentioned, and, according to Seibert,[1] may closely resemble those of meningitis, of malarial affections, and of typhus fever.

Sometimes gastric catarrh and dyspepsia produce curious nervous disturbances. Convulsive seizures as the result of gastric and intestinal disorders are too well known to require much more than a passing reference. The convulsion may be tetanic or clonic, or even both states may be present. Most commonly it is first tonic, then clonic. The child is left much exhausted when the attack has passed by, and often falls into a state of collapse and unconsciousness, or else is seen by the physician staring wildly about, with anxiety strongly depicted on its face.

---

[1] Jahrbuch f. Kinderheilkunde, xxvi., H. 3 u. 4, p. 348.

There is a much more rare set of nervous disorders, however, set up frequently by these states. Localized or diffuse clonic movements sometimes appear. Dizziness may be present, and high fever or an abnormally low temperature may mark the aberrant functions of the nervous system. Aphasia has been recorded as present in several cases. Thus, Henoch[1] mentions an instance of a girl of two years in whom total aphasia came on in an hour, so that pinching could call forth no word from the child but the sound "Au!" The aphasia passed away an hour later, speech returning perfectly after the vomiting of some cherries.

Another instance is that of a boy who had overloaded his stomach with food, and in consequence was seized in the night with severe colic and a liquid, ill-smelling diarrhœa. In the morning, after a deep sleep, he also could only make the sound "Au!" when he was pinched. By the following day he was well, but was at first bewildered and mentally disturbed. A third case was virtually identical with that just given. Siegmund records[2] a case occurring in a nine-year-old girl, in whom vomiting came on spontaneously, and in whom aphasia passed off as soon as the stomach was relieved.

The organs of respiration also suffer from similar reflex disturbances. In children who are prone to spasmodic croup a potent cause of the affection is indigestion, and both adults and children often have dyspeptic or gastric asthma.

Fraenkel[3] records a case of hemiplegia brought on by gastric irritation in a four-year-old girl who had eaten large amounts of "table-food." Half an hour after eating she lost the power of movement and sensation on the right side. Even the right conjunctiva was anæsthetic. The next day recovery occurred. Sensation returned first, and shortly afterwards the power of movement was restored.

Diagnosis.—It is comparatively easy in the first or early attacks to separate this state from many others of disordered alimentary function, and if the history as to the cause is clear the difficulty is much decreased. In some instances, however, the vomiting, with its retching, may resemble that of meningeal tuberculosis, from which it is to be separated by the history, appearance, and prolongation of the attack, as well as by the mental and nervous symptoms. Again, typhoid fever of a mild type may be represented if the attack is prolonged, and the very indefiniteness of the acute paroxysms may cause them to be mistaken for the forerunners of some acute contagious malady.

Prognosis.—The prognosis of acute gastric catarrh is invariably favorable unless the predisposing state endangers life in itself or the attack passes on to a more serious lesion. It is very common for relapses to occur during convalescence, and even after recovery seems complete.

[2] Discussion of Henoch's paper in the Medical Society (loc. cit.).

[3] Schmidt's Jahrbücher, 1883, 2, ii. 261.

Treatment.—By far the most important point in the treatment of acute gastric catarrh is the regulation of the diet. This may be divided into two parts,—first, the regulation of the food during convalescence or during the attack, and second, the character of the food to be used during the interval following one attack and preceding the next. Total abstinence in the acute stages of the attack, and absolute bodily and mental quietude, are advisable. There are several reasons for this. In the first place, the juices of the stomach are in an abnormal state and unfit to receive more food. Secondly, the mucous membrane of the stomach is already hyperæmic from the inflammation, and, as the normal viscus takes on a physiological hyperæmia on the ingestion of food, we should add to the injection of the blood-vessels did we allow more nourishment to enter the viscus. Last of all, the excess of the mucus and lactic and butyric acids present renders any new food impure before it can be assimilated, and so prolongs the trouble. As the attack passes off, small amounts of food may be given, readily digestible and not likely to become easily decomposed or rendered acrid by the mucus in the stomach. Milk with a large percentage of lime-water is to be used, since the alkali not only prevents a too firm coagulation, but also decreases the secretion and action of the mucus. The thirst may be excessive, although anorexia is complete, and small pieces of ice may be administered for its relief. Commonly it will be found that the patient rapidly improves up to a certain point, then stops or relapses. This is due to the accumulation of mucus, which undergoes fermentation, and, if marked evidences of the presence of this secretion are given, a mild and gently-acting emetic may be employed to dislodge the fermenting mass. Sodium bicarbonate with compound infusion or compound tincture of gentian may be used in convalescence, and small sips of effervescing draughts are useful. If constipation exists and vomiting forbids the use of the ordinary purgatives, a Seidlitz powder divided into fourths or fifths and taken in this way every fifteen minutes or half-hour will settle the stomach, move the bowels, and often carry away mucus.

If there is much epigastric distress, a spice poultice is often of service.

Sweets and starches are to be rigidly denied the patient. If anæmia exists, iron may be used; but this is rarely needed.

The abdomen should be carefully protected with flannel, and draughts and unsanitary surroundings avoided.

The use of pepsin and of hydrochloric acid is to be much more thoroughly attended to than has heretofore been the custom. As a rule, we are apt to forget that pepsin acts largely by catalysis, and that it is not secreted as pepsin, but as pepsinogen, a substance which is changed into pepsin in the presence of an acid. For this reason hydrochloric acid should be freely employed, and pepsin given in large or small quantity according as there is reason to believe this ferment to be in normal or abnormal amount.

Common salt (sodium chloride) is virtually identical in its ultimate influence with hydrochloric acid, and should be always used, in moderation, with the food.

STENOSIS OF THE PYLORUS.

Synonymes.—Hypertrophic pyloric stenosis (Lebert),[1] Fibroid degeneration of the pylorus (Habershon).[2]

Definition.—A condition of the pyloric opening of the stomach characterized by a thickening of one or more of the coats of the viscus at this point. In some instances in adults it has been thought to be due to cicatrices formed by old ulcers, or to the ingestion of irritants, but in children it is never due to this cause, in all probability, owing to the extreme rarity of ulcer and cancer and of the ingestion of an irritant poison.

It must be understood that such factors produce stenosis of another type than that of which I speak, which is an idiopathic thickening or hypertrophy, independent of other diseased states, or existing as a congenital defect.

Clinical History.—Be the causes of stenosis what they may, it is impossible to differentiate one variety from another during life by the direct symptoms produced, although the condition of the patient may, by reason of other signs, point to the character of the obstruction, as, for example, the cachexia of cancer or the history of hæmatemesis in gastric ulcer. If the stricture is complete, so as to prevent the flow of the gastric contents into the duodenum, death very rapidly ensues, being preceded by a train of symptoms characteristic of obstruction of the alimentary canal, and consisting in violent vomiting, tympanites of an epigastric type, and generally a comparatively receding abdomen, owing to the prevention of the entrance into it of food. If the occlusion is congenital and the opening is closed from the first, this latter symptom is particularly noticeable, and under these circumstances the case passes through a more or less rapid course to death, a result which is reached quickly or otherwise according to the constitution of the child. Collapse always comes on as the case progresses.

Pyloric stenosis in children, even of a congenital type, is exceedingly rare, and partial narrowing of the pylorus is seldom seen. It has been a favorite theory that pyloric stenosis as found in the adult is congenital in origin; but, while the adult pylorus has been frequently found narrowed, the instances of this condition reported as having been found in children have been much fewer in number, proving that the state is not so largely congenital as had been thought. Very recently, however, Hirschsprung[3] has reported two interesting cases of this character. In one of these an apparently healthy infant, well grown and developed, died on the thirtieth day of life in collapse, having previously suffered with frequent vomiting and small and infrequent stools. The vomited matters never contained bile. The child was entirely breast-fed. The autopsy showed the stomach to be distended, its walls thickened, and the pyloric portion firm and enlarged to the extent of an inch. The opening would allow only a small sound to pass through. The muscular layer was deformed, and the mucous membrane was hypertrophied. In the second case tuberculosis was the cause of death at six months of age, and the autopsy revealed a somewhat dilated stomach, both the muscular and the mucous layer being thicker and harder than normal. This change extended over the entire stomach, but affected the pylorus particularly, the pyloric opening being very narrow.

[1] Die Krankheiten des Magens, Tübingen, 1878.

[2] Diseases of the Abdomen, London, 1862.

[3] Jahrbuch f. Kinderheilkunde, Bd. xxviii. H. 1.

There was a previous history of prolonged vomiting, but it may have been due to the tuberculosis. As Hirschsprung points out, the child might, so far as the gastric lesion was concerned, have reached adult life.

Neale[1] records a case of imperforate pylorus in which the stomach soon after birth rejected all food, and the child died of inanition and exhaustion. After death the pyloric opening was found congenitally closed.

Goldenhorn and Kolatschewski[2] record a case of pyloric stenosis producing great gastric dilatation and dependent upon a polypoid tumor of the mucous membrane of the pylorus.

Wünsche, Andral, Förster, and Bull have also recorded such cases.

Pathological Anatomy.—So few cases of this disease in children are recorded that our pathological knowledge must be derived largely from the condition in adults. In such persons it is generally found, as in the cases of Hirschsprung, that more than one coat is involved in the change, although sometimes only a single coat is at fault.

Cirrhosis of the stomach has been confused with this lesion, and except for the confinement of the disease to this particular area the changes are very closely allied to each other. The submucous coat frequently has an increase in its connective-tissue elements, and the muscular coat is truly hypertrophied, partly, perhaps, as the result of the trophic change, and partly by the endeavor on the part of this coat to force the gastric contents through the narrowed orifice of the pylorus.

Diagnosis.—The constant distention of the stomach, the progressive failure in nutrition, and the repeated and uncontrollable vomiting, along with the absence of stools or their exceedingly small quantity, are sufficient to cause grave suspicion of such a state, or of obstruction in the duodenum or a little lower down. In some cases the enlarged pylorus may be felt through the walls of the belly, but the distention of the stomach generally forbids this. Ulcer, and cancer producing stenosis, may be excluded by reason of their rarity : the disease itself, however, is of very infrequent occurrence.

---

[1] Lancet, London, June 7, 1884.

[2] Berliner Klinische Wochenschrift, 1888, xxv. 51.

Prognosis.—Total occlusion is necessarily fatal. In partial occlusion the possibility of saving life is very slight.

Treatment.—To allay the vomiting, small doses of opium may be used, and, if the stricture be not complete, food should be given which is ready for assimilation, and in very small amount. Rectal enemata may be employed, and stimulants may be freely used. The question of operation for the relief of pyloric stenosis is hardly to be thought of in very young children, for, aside from the shock of so radical a measure, the possibility of any gain by interference is exceedingly slight. If congenital stenosis is present, as is, of course, most likely to be the case under the circumstances named, there is no telling what other abnormal states complicate it, and the prognosis is correspondingly obscure.

If, however, in any case the diagnosis is clearly of obstruction of the pylorus, operative procedures are to be attempted, with the distinct understanding that the procedure is but the chance of a forlorn hope.

DILATATION OF THE STOMACH.

Synonymes.—Gastrectasia, Gastric ectasy, Gastric dilatation, Dilatatio ventriculi.

Definition.—A condition of the stomach in which there is marked laxity or dilatation of its walls, generally uniform in its distribution, but often greatest at the cardiac end. It is to be most carefully separated from the condition, so commonly seen in children, which depends for its presence on imperfect digestion both gastric and intestinal, accompanied by enlargement of the entire belly and with no absolute increase in the capacity of the abdominal viscera. Very frequently gastric distention due to the accumulation of food or gases is mistaken for the state in which an absolute increase in the diameters and capacity of the stomach is present. Cases of this character of gastric distention are often called cases of functional dilatation.[1]

History.—Gastric dilatation has been recognized as a common and distinct morbid state for very many years, in both adults and children, but the latter class of cases have been thought to be rare.[2] Though the literature of the subject in respect to children is far more limited than is that devoted to adults, yet we already have a large number of cases recorded, and several authors by their communications have placed before us a very complete study of the disease. Chief among these may be mentioned Thiebaut,[3] Comby,[4] and Moncorvo.[5] Comby alone gives the history, in a very full manner, of no fewer than forty-three cases occurring in children as young as two and one-half months of age, and upward. In addition to the authors already quoted we have Widerhofer,[1] who records a case occurring in a twelve-year-old girl, in whom the dilatation was great but the cause thereof ill defined. Lafage [2] reports two cases, one at ten years and another at sixteen years; while Demme,[3] of Bern, records an enormous dilatation of the stomach at six and a half years, as does also Pauli.[4] In this instance the supposed cause was congenital stenosis.

Clifford Allbutt,[5] after stating that gastric dilatation is much more common in children than is generally thought, details two typical cases, one in a boy of three or four years, the other in a boy of ten years. In our own case, represented in the accompanying photo-plate, the age of the child was eighteen months.

Etiology.—This disease in the child has for its factors several conditions, both local and systemic. In the first place, stenosis of the pylorus may, by its partial obstruction to the flow of food, dam back a large amount of ingesta, which, as it increases in bulk, requires more space and gradually distends the gastric walls to such an extent as to produce partial palsy of their muscular coats at the very time when increase in muscular power is needed to overcome the obstruction. At the same time the delay in the evacuation of the viscus causes the development of a certain quantity of gas. As the result of fermentative changes, the chemical reaction of the mass is no longer normal, while the mucous membrane, becoming irritated, may add to the abnormality of the contents of the stomach by secreting a mucous coating which covers it and the semi-digested food.

How frequently stenosis is actually present as a factor is difficult to determine. As we have already pointed out, in the section on this disease, it is not a common lesion in childhood, even if it be congenital, and there are unfortunately not only very few cases of this character reported which have been confirmed by autopsy, but still fewer which have been found in conjunction with dilatation on the post-mortem table. There is no doubt of the ability of pyloric stenosis to produce dilatation of the stomach: the only question is as to the frequency of its own occurrence.

Another local cause is inherent atony or weakness of the gastric walls, a condition very common in rachitis of an advanced type. Under these circumstances there is lacking that force which is necessary for the carrying out of the two physiological functions of the organ,—namely, the rolling of the food backward and forward for its thorough infiltration by the gastric juice, and its ultimate expulsion into the duodenum. Rickets is so closely associated with bad feeding that there can be no doubt that the muscular walls of the stomach are influenced not only by the general systemic state known as rachitis, but also by the direct involvement of the walls themselves.

[4] De Ventriculi Dilatatione, Frankfurt, 1839.

[5] Proceedings of the Medical Society of London, vol. xi., 1887 and 1888.

If the food be poor in quality the hunger of the child often leads it to over-distend the stomach time after time in order to obtain sufficient nourishment, and this over-distention and malnutrition soon increase the capacity of the organ. Indeed, it is stated that the muscular fibres of the fundus of the stomach in artificially-fed children are very commonly weak, so that from the earliest period of life there may be a tendency to dilatation.

While the stenotic state of the pylorus produces a purely mechanical expansion of the gastric walls, atony of the stomach may be considered as resulting in an imperfectly-carried-out physiological act, the consequences of which are in the end virtually identical with those of stenosis. Not only is this true, but the gastric disorders of digestion and fermentation come on rapidly and with great severity, since the digestive function of the stomach is quite as atonic as that of the muscular layers.

Tuberculosis of this organ may be a cause, owing to the weakness thus produced, and, as gastric tuberculosis is by no means rare, this possibility is not to be overlooked. Rilliet and Barthez found the stomach involved in twenty-one out of forty-six cases of tuberculosis which they examined.

Secondary dilatation from the adynamia of asthenic states and fevers may be present in children as well as in adults, and marasmus, chlorosis, cachexia, and anæmia may so result. Hygienic surroundings which produce all these states are, therefore, a cause. Moncorvo[1] even states that malaria may be a cause.

Ulcers of a tubercular or ordinary nature situated in the stomach may so result, but their occurrence is excessively rare in children.

Chronic gastric catarrh may also be a cause of dilatation, by reason of the delay in digestion and the consequent closure of the pyloric opening until the act is completed. Welch asserts that chronic gastric catarrh may produce a paretic state of the muscular layers, just as is seen in laryngitis or corresponding lesions. In adults atrophy of the muscles has been noted as a cause, but it has not been recorded as present in childhood, and Edinger[2] states that amyloid changes may occur with such a result.

No evidence exists of atrophy and paresis of the stomach resulting from peripheral or centric nervous lesions and followed by dilatation, although Machon[3] and Thiebaut[4] assert that cerebral diseases may produce it. Machon also asserts that the child's stomach shows in every instance a relatively defective development of the fundus and a greater diameter than normal of the œsophageal orifice; while the muscular coats and peptic glands are poorly developed, the mucous glands are well formed; in other words, all the conditions tending to ectasy are present. Thiebaut also asserts that cardiac disease and repeated vomiting may produce gastric ectasy, and that adhesions outside of the pylorus may have a similar effect.

[4] Thèse de Nancy, 1881.

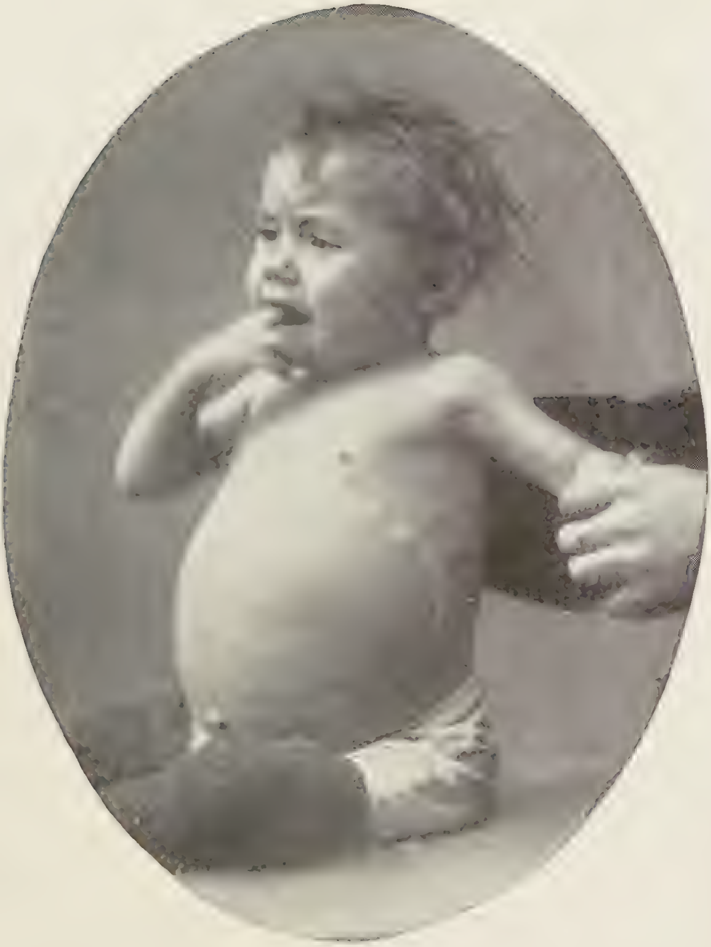
Kundrat and Widerhofer believe that overfeeding is a cause of considerable importance, and they assert that dilatation is not uncommon in children as a result of this.

Pathological Anatomy.—We have virtually no details as to the exact size of dilated stomachs in children. That enormous enlargements do occur, as in adults, is, of course, true, but further than this all remarks are based on theory alone. There is a certain change, however, which, as it occurs in adults, should be recorded as a possibility in childhood,—namely, muscular hypertrophy along with dilatation; and this formation is particularly apt to occur where stenosis produces dilatation. On the other hand, the wall may be atrophied. No degenerative changes are found in the muscular walls, as a rule. As the normal stomach varies so widely in size and shape, care should be exercised at the autopsy that a false diagnosis be not made.

Symptoms.—Aside from the general symptoms of disordered digestion, commonly considered under the title of dyspepsia, there are symptoms which are particularly marked in gastrectasia. In the early stages there is great thirst and loss of appetite, with persistent coated tongue and emaciation. Absolute repugnance to food, amounting at last to total refusal, finally comes on, but if the child be breast-fed or bottle-fed it will often take milk in order to relieve the thirst. Vomiting is always a prominent symptom, the matters vomited being often greenish and extremely fetid, and nearly always profuse in amount. Examination of the ejecta will generally show food swallowed days before, owing to the imperfect digestive action of the stomach, and this very inability of the stomach to act on the food generally gives, for a long period of time, a sense of weight and fulness often amounting to pain, and complained of bitterly if the child be old enough to define the sensation. There is tenderness over the epigastrium on pressure, and the displacement produced by the palpation often brings on either acid or yeasty eructations or even the vomiting already named. Nausea preceding the vomiting is by no means common, there being simply a gush of foul liquids from the mouth. After such an occurrence the vomiting fails to recur for from twenty-four to forty-eight hours, —*i.e.*, until the viscus becomes overladen once more. The gases which are given off on eructation are exceedingly acrid, nauseous, and bitter. Sometimes they are offensive, but more rarely odorless. No analysis of these gases has, so far as we are aware, been made in children, but in adults they have been found inflammable. They consist of oxygen, nitrogen, hydrogen, and carbonic acid. Sometimes sulphuretted hydrogen is present in large quantity.[1] The reaction of the vomit is almost always acid, lactic and butyric being the acids most commonly found. Fibres or masses of semi-digested and semi-decomposed food can be seen by the naked eye or

---

[1] Ewald, in Reichert und Du-Bois Reymond's Archiv for 1874, p. 222, gives an analysis of one of Frerichs's adult cases, in which the amount of carbonic acid was 17.40, hydrogen 21.52, marsh gas 2.71, olefiant gas traces.



Case showing Area of Flatness on Percussion when the Stomach is distended.

under the microscope, and sarcinæ and many forms of bacteria swarm in the mass. Particular search should be made for the yeast-fungus, Torula cerevisiæ, the presence of which is a certain evidence of active fermentation. The condition of the bowels is almost invariably that of advanced constipation, and this state is largely dependent upon the small amount of food which escapes into the duodenum, the general debility and lack of exercise, and the pressure upon the transverse and the ascending colon.

The complications of gastric ectasy in children may be exceedingly various, owing to the notorious irritability of the nervous system. Convulsions of a tetanic or more commonly of an epileptiform character may come on during the periods of over-distention or immediately after an attack of vomiting. Sleep is often disturbed and restless, and the wakefulness may even amount to total insomnia. Emaciation becomes extreme, but the wasting is gradual rather than rapid, owing to the fact that some parts of the ingested matters are assimilated during the period of gastric quiescence. Anæmia is generally far advanced. The limbs are wasted, the legs particularly showing, by comparison with the swollen epigastrium, their lack of flesh. The skin hangs loosely everywhere save over the affected area, where it is tightened almost to the point of bursting. The abdominal surface is often covered by engorged and multitudinous veins, which on pressure show themselves to be carrying the blood-stream from below upward. Borborygmus is sometimes startlingly loud and prolonged, and seems to last for minutes at a time, rarely accompanied by pain. Constipation is always present, but if laxatives or purges are given they bring on a gush of partially-digested food and liquid from the rectal opening which is remarkable because of its volume. It is often blackish and always horribly offensive, flowing from the diaper over the child and its clothing. Commonly, if the child be young enough to take only a milk diet, large cheesy morsels are seen in the stools. Peristaltic waves can be seen as they pass along the wall of the stomach itself, on the epigastric surface, which may be made more marked by the application externally of heat or cold, or by draughts of cold water. In respect to adults, however, Francon[1] asserts, as does also Thomson, that this sign is present only when pyloric stenosis exists. The liver and other abdominal organs are rarely either swollen or decreased in size, except indirectly by the general malnutrition.

As an indirect, reflex symptom of this disorder, Blache[2] speaks of night-terrors, and asserts that dyspnœa and cardiac palpitations may be developed in such cases.

Diagnosis.—Inspection shows a distended and tense belly, highly tympanitic in the upper portion on percussion, or, if the ingesta be in large amount, dulness may be developed. The belly is so distended at the upper part as to have been called "frog-belly" by the Germans and the French.

---

[1] Lyon Médical, 1887.

[2] Revue mensuelle des Maladies de l'Enfant, February, 1886.

Penzoldt has proposed the pouring of so much water into the stomach as to distend it completely, and then by means of percussion to define its boundaries and thereby obtain some idea of its dimensions; but, as Pacanowski[1] has pointed out, such a procedure would be dangerous if ulcer be present. This scarcely holds as an objection in children, owing to the rarity of ulcer, but it is a means of diagnosis which children in America and England can hardly be subjected to, and is certainly harmful to some degree. Lente has proposed the introduction of a sound which may be twisted around while one hand follows it through the abdominal walls; but this method is, to say the least, heroic.

Again, it has been proposed by Frerichs and Moncorvo to make a diagnosis by what the latter calls "plessimetric gastro-resonance," which consists in the ingestion of several grains of bicarbonate of sodium and four grains of tartaric acid followed by two tumblerfuls of water. This is a method which I believe to be absolutely unjustifiable.

By far the most important point to be decided, after that of the existence of dilatation, is how far the lower edge of the stomach has been carried downward; for it is worthy of remark that the upper surface rarely alters its position very greatly, although it may be pressed up against the diaphragm, rendering any attempt to percuss its upper outline almost impossible, owing to the liver and ribs, or even the lung, being in the way. In some cases the diaphragm is so displaced as to become useless as a respiratory muscle. Oftentimes the lower border of such a stomach may pass as low as the navel, or even to the pubes. Obrastzow[2] states, as a differential point between the gastric outline in adults and in children, that in the latter under the age of fifteen years the lower border seldom reaches to the navel, while it may do so in the adult. The position of the stomach in the young child is so entirely different from that of the adult that the same outline of resonance or dulness is not to be looked for as it would be in a grown person. In the child the stomach is scarcely more than a dilatation in the course of the alimentary canal, and as such the pyloric end of the stomach is much lower than the cardiac extremity. Further than this, the fundus is virtually absent in children. There are other points to be remembered of an anatomico-physi-

FIG. 1.

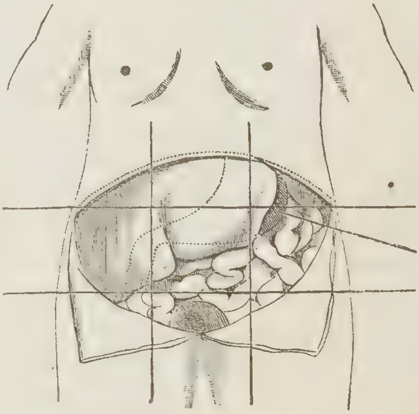


Diagram showing the position of the stomach and liver in a child of about two and a half months. Dotted line shows outline of stomach, which is partly covered by the liver.

---

[2] Ibid., 1888, xliii., 4 and 5, p. 417.

ological character which apply to both the adult and the child and are frequently overlooked,—points which make the area of resonance when the stomach contains no food at variance with the area when it does contain solids and gives dulness on percussion.

When the stomach is empty the great curvature is directed downward and the lesser upward; but when the organ is full it rotates on an axis running horizontally through the pylorus and cardia, so that the great curvature appears to be directed to the front and the lesser backward. Although this movement is largely absent in very young children, it increases very rapidly as growth goes on, and probably is always established at the end of the second or third year.

Fig. 2.

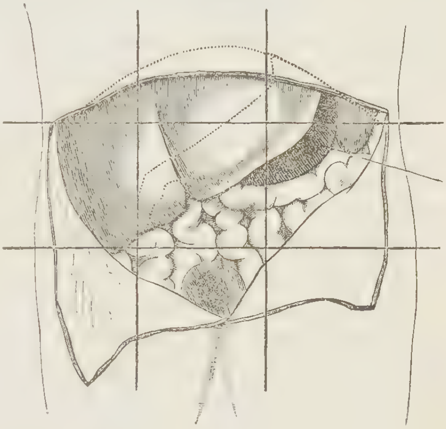

Diagram showing position of stomach in a child of four months. Dotted line shows outline of the viscus, which is partly covered by the liver.

Auscultation may, on shaking, give a well-developed succession-sound, while gurgling is exceedingly common. As, however, succussion is commonly heard in nearly all stomachs, much importance is not to be attached to this sign.

Severe dilatation of the stomach in childhood separates itself so clearly from almost every other state that a differentiation is not needed. Moderate dilatation, which is more common and therefore more important of recognition, is far more difficult of diagnosis, and yet can be separated from other states if care is exercised. From enlargement of the liver it is to be separated by the difference in the area involved on inspection, and by the all-important fact that in liver-enlargement the percussion-note is dull or flat, whereas in dilatation the sound elicited on percussion is generally tympanitic, unless the stomach is filled with food. The great exception to this rule is found when no vomiting has occurred for some days, when, by reason of the accumulation of liquid in the stomach, a flat note may be obtained. While the percussion-note may not be always completely diagnostic, it may be made more so by changing the position of the body, as in pleurisy. Palpation is also of great value, the hard, smooth surface of an enlarged liver being distinctly characteristic, while the more yielding but tense sensation given to the fingers and hand in dilated stomach can by no possibility be taken for that imparted by a solid organ. Splenic enlargements may be separated from dilated stomach in the same manner. Again, the area of dulness from enlargement of these two organs is constant, while that of dilatation varies with the quantity of food and liquid, and can always be increased by the ingestion of large amounts of water. Disease of the pancreas occurs so rarely that it cannot be regarded as a probable condition, and there is never produced under these circumstances the same train of symptoms in both states. Dilatation of the colon is not to be forgotten, since it gives many similar signs.

Dropsy and ascites may, of course, be mistaken for dilatation of the stomach, but the presence of greater bulging in the lower third of the abdomen than in the epigastrium, and the fact that dropsical effusions may be found elsewhere, will aid in the differentiation. Succussion is not marked in ascites, and there is commonly in this state some evidence of heart-disease, of renal disease, or of tumor pressing on the large venous trunks.

Catarrhs of the intestinal mucous membrane associated with fermentative changes and distentions by flatulence produce deformity in the suprapubic rather than in the epigastric area, and are accompanied by other symptoms too well marked to be overlooked, such as mucous diarrhœa, colic, and perhaps lientery. The latter condition, too, is not so chronic, nor so slow in its onset.

As an aid to diagnosis the question of the capacity of a child's stomach at different ages is an interesting one, since it may be possible to gain by lavage or emesis some idea of the capacity of the individual stomach before us, and thus discover whether there is any difference from the normal. Benke[1] states that the capacity of the new-born child's stomach is from thirty-five to forty-three cubic centimetres, at fourteen days it is from one hundred and fifty-three to one hundred and sixty cubic centimetres, and at two years it reaches seven hundred and forty cubic centimetres. These results are not in accord with those of Townsend given by Rotch in the first volume of this Cyclopædia: he found the stomach of a child of five days to hold only twenty-five cubic centimetres. Rotch states that the capacity at twelve months is one hundred and twenty cubic centimetres.

According to the studies of Frolowsky,[2] the activity of growth in gastric capacity can be represented by the ratio of one for the first week to two and a half for the fourth week and three and one-fifth for the eighth week. It is only three and one-third for the twelfth week, three and four-sevenths for the sixteenth week, and three and three-fifths for the twentieth week. In this connection the diagrams Fig. 1, page 291, Fig. 3, page 296, and Fig. 4, page 297, in Dr. Rotch's article in the first volume of this work, are of interest.

Prognosis.—The prognosis is always unfavorable, but it is more favorable in children than in adults, as the distention may cease and the child grow up to its stomach. The great danger in children lies in inanition and exhaustion.

Treatment.—The treatment of dilatation of the stomach may be divided into two varieties,—the first consisting of the methods of cure which are directed against the state of the gastric walls themselves; the second, of those methods in which abnormal changes in the food and the gastric contents and secretions are combated, thereby allowing reparative changes to take place. As has already been said, dilatation of the stomach may be dependent upon either some constitutional or some local cause. If the cause be rickets, it is evident that the malnutrition of the bony system and of the system in general is to be improved, and that remedies devoted to this object are to be given,—cod-liver oil by inunctions, or, if the digestive apparatus will bear it, by the stomach. Lacto-phosphate of lime, phosphate of sodium, or iron, often in the form of the syrup of the iodide, should be used if any signs of struma are present. Good foods, possessing large amounts of salts, yet easy of digestion, are, under these circumstances, particularly desirable, and by far the larger part of the treatment should be directed to the dietetics of the case. Of this I shall speak farther on.

---

[1] Ueber die Capacität des Magens Neugeborenen: see Deutsche Med. Wochenschrift, vi., 32, p. 433, also 33, p. 448.

[2] Inaugural Dissertation, St. Petersburg, 1876.

There are several means to be employed for the relief of gastric dilatation other than those which can be called medical, so far as drugs are concerned.

These consist, first, in efforts to evacuate the stomach and to cleanse it; secondly, in attempts by these and other means to prevent its distention by the gases which arise or by the accumulation of ingesta which takes place; thirdly, in the regulation of the diet so as to avoid causes which have a tendency to increase the disorder.

Dilatation of the stomach is so difficult to cure that very satisfactory results are not to be looked forward to, but nevertheless the nutrition and the general state of health are to be carefully considered.

Taking up *seriatim* the non-medicinal means which we have named, we come at once to the consideration of lavage, a method which has been resorted to with most thorough trial on the continent of Europe. Originally proposed by Epotius in 1863, it has been most widely employed in children by Epstein,[1] who in one article alone records its employment in two hundred and eighty-six cases of gastric disease in infancy, the patients being less than one year of age.

Epstein employs a No. 8 or a No. 10 Nélaton catheter for the tube, and warm water holding in solution a little benzoate of magnesium, the latter being resorted to chiefly when fermentation- and decomposition-products are present. If none of these conditions are present, ordinary water will usually suffice. The liquid employed should always be warmed. Others —as, for example, Lorez[2]—use the ordinary English catheter, of the size known as No. 11 or No. 12. The question as to the variety of tube to be employed is a vital one, since a poorly-devised apparatus not only gives no relief, but disgusts both the patient and the physician with the technique of the method. The tube should be more like a hollow bougie than like a catheter, in order that its calibre may be great enough to carry off some of the semi-solid matters present. If this rule is not carried out, two evil results follow. In the first place, the tube and its apertures rapidly, or even at once, become clogged; secondly, the liquid is drained away, leaving behind a mass which is semi-solid, to be sure, and less bulky, but which is nevertheless the quintessence of the nastiness of fermentation, and quite as qualified to leaven any fresh food on its entrance as the liquid would be.

---

[1] Virchow's Jahresbericht, June, 1883 (abstract); original article in Arch. für Kinderheilkunde, Bd. iv. S. 325.

[2] Arch. de Patol. Infantil, July, 1888.

The holes in the gastric end of the tube should therefore be large enough to take in fairly large masses. In some cases the ordinary siphon may be used, but where there is any solid food or resistance, suction by means of a stomach-pump is necessary. The tube should be, for a child, twenty-four or thirty inches in length. The methods by which lavage is employed, further than those we have named, are as follows. The catheter or tube should be passed backward against the roof of the mouth, so that by following the curve of the hard and soft palates it is directed into the pharynx and œsophagus, and then by gentle pressure forced on down into the stomach. The irritability of the pharynx rapidly disappears, and it is surprising how quickly the patient may become accustomed to the operation and submit to it without any feeling of discomfort. After the tube has reached the stomach, a small funnel is to be fitted in its external end, which is then held above the head of the patient while water prepared in the way we have mentioned is poured into it until the stomach is filled, when the funnel end is lowered and the stomach is emptied by siphonage.

The stomach-pump has one very serious disadvantage, which is present with even more force in the child than in the adult,—namely, the danger of injury to the coats of the organ. This apparatus is also more costly and cumbersome, and for children the siphon is powerful enough in its action to take away all excuse for the use of the more complicated apparatus unless the contents of the stomach are in bulk.

It is particularly necessary in children, on account of the lack of intelligent aid and their liability to gulp, that every care should be taken that the tube does not slip entirely out of reach into the stomach, and for the prevention of this danger a string should be attached to the external end of the tube before it is introduced, and the tube should always be at least thirty inches in length.

The treatment of dilatation to be considered after lavage is dietetic. There can be no doubt that one of the chief reasons for the emaciation which comes on is the failure on the part of the stomach to digest and assimilate nourishment. In addition to this, the intestine is really the place for absorption of food to take place, and the delay in the stomach virtually makes the chyme unfit for the function of the small intestine.

The foods to be given are, of course, to be in the highest degree capable of ready assimilation, and should be confined, especially in severe cases, to the materials which we can readily predigest by the employment of the digestive ferments now so largely sold. Carefully-skimmed milk is valuable, aside from its inherent usefulness, in that it lacks the fats which can be utilized only in the intestines and which simply break down and decompose if kept in the stomach. Oyster broth, carefully freed from any oily matters in cooking, and thoroughly pancreatized, is to be given. These questions are, however, more thoroughly discussed in the articles on feeding, which may be found in the first volume of this work.

Rectal alimentation to some degree is always useful, particularly in older children, and Ewald, of Berlin, suggests the following nutrient enema: Beat up two eggs with a tablespoonful of cold water; to this add a little starch, boiled in half a cupful of a twenty-per-cent. solution of grape-sugar and a wineglassful of red wine. The solution is to be well mixed at a temperature not high enough to coagulate the albumen, and injected as high up into the bowel as possible. For a child this mixture should be somewhat less in quantity than that given above for the adult, particularly as to the wine.

An exceedingly important part of the dietetic treatment of gastric dilatation consists in the constant bearing in mind of the fact that the tendency of food is to accumulate, and the avoidance of the pernicious habit of adding solids or liquids to the quantity of ingesta still remaining from a previous meal. If the child is old enough, all the remains of previous feedings should be removed by lavage before anything more is given, since otherwise the sweet food is at once contaminated by the liquids which it meets in the stomach.

The medicinal treatment of gastric ectasy is, unfortunately, very limited so far as the stomach itself is concerned, and, indeed, we doubt whether any direct medication can ever be of much value unless in the form of disinfectant substances such as we have spoken of in studying lavage, and these only prevent decomposition of the food and do not effect a cure.

GASTRIC ULCER.

Definition.—An exceedingly rare affection in childhood, characterized by epigastric tenderness and the vomiting of blood, the gastric discomfort generally being increased by the ingestion of food. The essential lesion is an ulcer of varying size and depth situated somewhere on the gastric mucous membrane.

So rare is the affection that very few, in fact only one or two, of the text-books on the diseases of children refer to it, and, as the literature is so meagre, we are forced to give far less information than we should desire.

According to Descroizilles,[1] the symptoms are as follows. At an early stage of the disorder an anorexia develops itself, which is steadily progressive, so that it may become complete. Vomiting may come on, or in some instances nausea is the only symptom. Eructations and pain are also frequently present, and the ingestion of food, as in the adult, is generally followed by an exacerbation of the suffering.

In some cases, however, the symptoms are very aberrant, and the diagnosis is almost impossible in consequence. Indeed, Descroizilles asserts that under these circumstances there is nothing typical of the condition present.

---

[1] Pathologie et Clinique infantile, Paris, 1883.

Should perforation of a blood-vessel occur, there result great circulatory disturbance, violent pain, and abundant vomiting and purging of blood, followed more or less rapidly by collapse.

Etiology.—Most commonly gastric ulcer in childhood comes on as a complication of some of the more frequent diseases, such as pneumonia, tuberculosis, and purpura hæmorrhagica. Strumous states also predispose to its formation, and all conditions of asthenia are prime factors in its production. Typhoid fever has, for this reason, been stated to be a cause.

Pathology and Morbid Anatomy.—According to Descroizilles, the ulcer is rarely larger than a bean, but may be as large as a twenty-five-cent piece. While it is generally of a tuberculous nature, it is not so invariably, but may be due, as has been already stated, to other causes than systemic tuberculosis. The edges of the ulcer are irregular, and reddish or even yellow in color, and the depth of the lesion may be so slight as simply to invade the superficial mucous membrane, or it may dip down into the submucous coat, injuring blood-vessels in its course. By far the most voluminous statistics that we have in regard to its occurrence in both the child and the grown person are those of Welch, given in his masterly article on simple gastric ulcer in Pepper's "System of Medicine."[1]

In six hundred and seven cases of ulcer of the stomach found post mortem and collected by Rokitansky,[2] Starcke,[3] Lebert,[4] Chambers,[5] Habershon,[6] and Moore,[7] only one occurred between the ages of one and ten years, and thirty-two from ten to twenty years. Lebert found by diagnosis during life but one case between the ages of five and ten years in two hundred and forty-seven cases, and Rokitansky in his enormous experience saw only one instance of the disease under fourteen years of age.

Rehn[8] has analyzed all the cases up to 1874, and finds that only six or seven of the reported cases stand examination as cases of simple ulcer, and in these the ages varied from seven days to thirteen years. In the case of Busch[9] an ulcer was found on the anterior wall of the stomach of a boy aged seven days, as large as a one-cent piece, on the greater curvature near the pylorus; it extended in depth through the muscular coat to the serous.

The case of Binz[10] occurred in a girl of eleven days, the ulcer being situated on the smaller curvature between the fundus and the pylorus. That of Billiard[1] was in a child of fifteen days, and was placed in the pyloric third of the stomach on the greater curvature. In Donnes's case[2] healing of the ulcer occurred in a three-year-old girl, although it was the size of a ten-sous piece. It was situated on the upper half of the smaller curvature. Gunz[3] diagnosticated and found a simple ulcer at the pylorus on the greater curvature; while the case of Rubz[4] was in a thirteen-year-old girl, and was followed by perforation on the smaller curvature.

[10] Berliner Klinische Wochenschrift, 1865, Nos. 15 and 16.

Since the researches of Rehn were published, six more cases have been reported. Of these, Reimer[5] reports one in a child three and a half years old, Goodhart[6] one thirty hours after birth, Eröss[7] one in a girl of twelve years who was suffering from miliary tubercle and in whom the ulcer perforated the omental sac, and Malinow[8] one in a girl of ten years.

The fifth case is recorded by Barlow[9] as occurring in a child of twenty-one months. On the anterior wall of the stomach at the cardiac end, close to the greater curvature, there was an oval ulcer one-eighth to one-quarter of an inch broad. The edges of the space were undermined, and loss of substance extended almost to the peritoneum. There was no thickening around the spot, neither was there any evidence of tubercular change near by. Besides this ulcer there were two smaller ones on the greater curvature about in the middle zone of the stomach, and two others near the pylorus,—in all, no fewer than five distinct ulcers. There was miliary tuberculosis everywhere else in the body.

The sixth case is recorded by Talamon[10] as occurring in a child of four and a half years, which was under the care of Triboulet in the Hôpital Sainte-Eugénie. After death no fewer than seven tubercular ulcers were found scattered over the surface of the stomach, which was considerably dilated. Two ulcers were at the pylorus, two at the cardiac end of the stomach, and three on the greater curvature.

Curiously opposed to all this evidence is the statement made by several reliable investigators, notably by Buhl and Hecker,[11] Binz,[12] Spiegelberg,[13] and Landau,[14] that one of the most frequent causes of gastric hemorrhage in the new-born is ulcer of the stomach or duodenum dependent upon emboli from thrombosis in the umbilical vein. (See section on gastric hemorrhage.)

Prognosis.—The prognosis is unfavorable.

Treatment.—The treatment of gastric ulcer in children should be very much the same as that in adults, save in the fact that, as the lesion usually occurs in strumous and tubercular cases, attention is to be directed to the general health and to the use of those foods which will conduce to health and strength and at the same time not interfere too greatly with the stomach.

In the way of drugs internally we would recommend the alkalies and bismuth, or small doses of opium. Nitrate of silver in small amounts, frequently repeated, combined with belladonna or opium, is of great value in all such cases and should be persistently employed. Counter-irritation should be applied to the belly for the relief of the pain and tenderness and to relieve the local congestion and affect the morbid process favorably. This counter-irritation, in our opinion, should be of the mild continuous type rather than of the severe and fleeting character, and for this purpose the ordinary spice plaster, made of pepper, cinnamon, allspice, and cloves, may be employed. In the collapse following hemorrhage or perforation into the abdominal cavity, the cardiac stimulants should be carefully and guardedly administered, lest by an excessive action they increase the hemorrhage, while for the direct resuscitation of the patient external heat and rubbing of the extremities should be resorted to. Bordeaux wine, preferably of considerable age, should be employed as a stimulant if the use of alcohol is to be kept up for any time. In the early stages of the collapse the alcohol should be hot and fairly concentrated. If the patient is conscious, small pieces of ice may be swallowed to control the hemorrhage, and ergot may be given with the same object in view.

The vomiting should be stopped, since it may increase the hemorrhage, and for this purpose the usual remedies are to be employed, including both those which act centrically and those which act peripherally. Bromide of sodium in weak solution may be injected into the rectum for this purpose.

In regard to the diet, it should be light and easily assimilated, and should be one whose chief digestion and assimilation will be intestinal, not gastric, since by this means we largely avoid the exposure of the raw surface of the ulcer to the acid gastric juices. In some cases the patient should be fed only by the rectum, by means of artificially digested food, which is very useful also when given by the stomach.

GASTRIC CANCER.

Synonyme.—Carcinoma of the stomach.

Primary gastric cancer is an exceedingly rare disease in childhood, and in reality exists only as a medical curiosity. Steiner and Neureutter[1] failed to find a single instance of it in two thousand autopsies made upon children, notwithstanding the fact that the lesion was particularly sought for. A similar experience has been reported by pathologists all over the world, the only instances which we have been able to find being those of Cullingworth,[1] Kaulich,[2] Wilkinson,[3] and Scheffer.[4] In the first of these a cylindrical-celled epithelioma was found in the stomach of a child of but five weeks, and the extreme youth of the subject has led Welch[5]—with justice, we think—to the conclusion that the growth must have been congenital. The case of Kaulich was in a child of one and a half years, and, as all the other organs were involved, it is doubtful whether the disease was primary in the stomach. Wilkinson's case is still more open to question, as it is by no means positive that the disease was not a mere hypertrophy. The case of Scheffer was an encephaloid mass, found by Recklinghausen, with secondary involvement of the spleen. Another case which should perhaps be included in the list is that of Jackson,[6] occurring in a boy of fifteen years, in whom no symptoms appeared till within ten weeks of death.

---

[1] Prager Vierteljahrschrift, vol. lxxxix. p. 77.

Widerhofer's[7] case, sometimes recorded as one of cancer, was probably secondary from retro-peritoneal sarcoma.

Symptoms.—The symptoms of gastric cancer in children are to be gathered only from the isolated cases which have been reported, and from the symptoms as they appear in the adult.

Pain is, of course, one of the most marked signs of the disease, and is lancinating and of a severe character, extending to the hypochondrium or downward towards the umbilicus. The rest at night is much broken, and loss of appetite is a prominent symptom from a very early period in the course of the malady. Vomiting of the food, with or without blood, may be a symptom, and there is always a high grade of wasting and cachexia. Irregular intermittent attacks of fever are common, and if the growth is properly situated or large there may be more or less dyspnœa.

The treatment of gastric cancer is, of course, directed solely to the relief of pain and the comfort of the sufferer. The diet should consist of easily-digested and softened food.

The prognosis is necessarily fatal, and the main effort should be to relieve pain by morphine and similar drugs.

HEMORRHAGE FROM THE STOMACH, AND HÆMATEMESIS.

Definition of Gastric Hemorrhage.—Gastric hemorrhage is, as its name implies, a condition in which, by reason of a solution of continuity in a blood-vessel wall, blood gains access to the cavity of the stomach. It is to be carefully separated from hæmatemesis, which is not necessarily associated with a break in a gastric blood-vessel, and is merely a term defining a symptom, not a lesion.

Thus, hæmatemesis may be due to the swallowing of blood from a wound in the mouth, the throat, or the lung, or even to the ingestion by a malingerer of the blood of some animal. True hemorrhage from the stomach is quite rare in childhood, some of the most common causes of its occurrence being purpura hæmorrhagica, the hemorrhagic diathesis, and kindred states. Aside from these causes, such an accident as the ingestion of sharp foreign bodies or of corrosive acids or alkalies may produce it. In girls about puberty such a symptom may be an evidence of a vicarious menstruation.

In very young children, gastric congestion the result of obstruction in the portal system or of inherent laxity of the gastric veins is a very common cause of the state known as *melæna neonatorum*, a gastric hemorrhage which frequently comes on during the first few days or weeks of life. It has been thought by some that a predisposing cause of this occurrence is difficult respiration after birth, resulting in general venous stasis; but this is hardly probable, since other vessels ought for the same reason to prove incompetent.

Leube states that the majority of these cases depend upon the existence of gastric and duodenal ulcers, but this would seem, from published statistics, very unlikely. On the other hand, Buhl and Hecker,[1] as well as Spiegelberg,[2] Binz,[3] and Landau,[4] assert that in the examinations made by them such lesions were almost always present. In a case of Landau's there was a thrombosis of the umbilical vein, and it has been asserted that, when the expansion of the chest takes place in the new-born child, small clots may escape from this vessel through the ductus arteriosus into the descending aorta and gastric arteries, and thus cause the formation of an ulcer in a manner similar to that which occurs in a round ulcer in the adult. Again, Landau believes that the same result may be reached by an embolus derived from the umbilical vein, which, being driven through the ductus venosus, enters finally the ductus arteriosus and descending aorta and so gives rise to gastric embolism.

As the researches of Cohnheim have clearly shown, venous stasis may cause oozing through the blood-vessel walls, and this may cause hæmatemesis.

In athrepsia in the new-born, Hutinal[5] states, there is to be found a normal gastric and intestinal epithelium, but always, where the wasting is acute, a dilatation of the small veins and passive congestion of the whole digestive tract. By this means the circulation is disordered, absorption is stopped, and secretion is altered. Rarely this goes on to hemorrhage from the dilated blood-vessels.

[5] Contribution à l'Étude des Troubles de la Circulation veineuse chez l'Enfant et en particulier chez le Nouveau-né, Hutinel, Paris, 1877.

Malarial fevers are capable of producing gastric hemorrhages as well as hemorrhages from the kidneys and intestines. Boon[1] has recorded a case in which gastric hemorrhage was the evidence of tertian ague and was cured by quinine.

Hemorrhages from the stomach may also occur in scurvy, yellow fever, and acute yellow atrophy of the liver, under which circumstances the leakage of blood depends upon the changes in the constitution of the blood itself. In the adult, females are by far the most commonly affected,—according to Handfield Jones,[2] in seventy-four per cent. of the cases. Whether this is true in children I do not know.

Symptoms.—Gastric hemorrhage may, if the amount of blood be very small, go on intermittently for long periods of time without notice, owing to the escape of the liquid into the bowel. If, however, the amount be large, the black, fetid, tarry stools will show its presence at once. If the hemorrhage be severe, long before its presence is evidenced by the stools, symptoms of loss of blood will assert themselves. In addition to the pallor and collapse always present, there will be oppression and a sense of weight in the stomach, finally going on into faintness and perhaps death. Vomiting sometimes comes on very early, and is typical of the disorder. If the hemorrhage be profuse and the vomiting be rapid in its onset, the blood expelled will be red and normal in hue. If the blood remain in the stomach for any length of time, it will be coffee-colored (coffee-ground), from the action on it of the gastric juice.

A very extraordinary accident sometimes occurs after gastric hemorrhage, and, while we know of no recorded case in the child, there is no reason why it should not occur,—namely, double permanent blindness. This amaurosis does not depend on the anæmia which causes this symptom so commonly in the parturient state, for it occurs where the hemorrhage is not severe enough to be noticeable, and does not leave when the system recovers its normal quantity of blood. Such instances are recorded by Fikentscher[3] and Von Graefe.[4]

Diagnosis.—If the amount of blood is very small, so that the vomit is very slightly tinged, the question at once arises as to whether the discoloration depends on hemorrhage or on some other cause. This can be determined by a microscopical examination, unless the blood is completely broken down. If this does not give us all the information we desire, we may resort to the test for hæmin,[1] as follows: Dry a small quantity of the blood at a low temperature, place a few particles of the dried mass on a glass slide, add two or three drops of glacial acetic acid and a small crystal of common salt, cover with a cover-glass, and heat gently over the flame of a spirit-lamp until bubbles of gas are given off. On cooling, crystals of hæmin appear.

After deciding that blood is present, it remains to be ascertained whether the blood is or is not directly from the stomach. The throat, mouth, and nose should be carefully examined, to discover any flow of blood from these places. I regard the posterior surface of the pharyngeal wall as a spot which should be carefully examined under these circumstances, because hemorrhages may very readily occur from this region from over-distended capillary vessels, and by the constant oozing ultimately cause the unconscious swallowing of a large amount of blood and at the same time make no show of a local clot or undue redness. Such a case was seen by me but a short time since.

By far the most common question for differential diagnosis lies between hæmoptysis and hæmatemesis. Thus, the former may cause the latter, or so much coughing may accompany the expulsion of the blood as to make it difficult to decide from which part the blood comes. If the vomit comes first and the cough secondarily, the hemorrhage is probably from the stomach. The absence of a history of pulmonary involvement and of pulmonary signs at the time of the attack, and the dark blood of hæmatemesis, separate it from hæmoptysis also. Again, the reaction of the blood of hæmatemesis is generally acid, while that of the blood of hæmoptysis is alkaline.

Prognosis.—This depends entirely upon the primary causes of the hemorrhage and upon the severity of the lesion producing it. If tuberculosis is the cause, the prognosis is hopeless. If, on the other hand, malaria or a kindred agency is at work, the case is more hopeful. The immediate danger of death from hemorrhage is not excessive.

Treatment.—The treatment of gastric hemorrhage is necessarily an immediate one, and after the active flow is past our attention must be turned to the prevention of other attacks. The methods to be followed with such a hemorrhage are almost identical with those applicable to all internal hemorrhages. Cardiac stimulants are to be avoided until the hemorrhage is completely controlled, for the same reasons that they are to be forbidden in external hemorrhages before the bleeding vessel is ligated. Perfect rest, flat on the back, is to be insisted upon. If the child is old enough to be frightened, his fears should be allayed by assurances of recovery, and every effort made to quiet any excitability of the patient and his friends, whose alarm often leads them to say things lacking in tact and calculated to disturb the needful rest. Probably the best styptic to be employed is Monsel's solution, in the dose of from one to three drops in a small amount of water. Tannic acid may also be freely given. It should not be forgotten, however, that these should not follow each other, as they are incompatible. Food should be withheld for several hours, in order that the clot may be thoroughly formed in the opening in the blood-vessel and not readily dissolved by the gastric juices. All coarse or hard foods, such as toasts or bread-crusts, are entirely out of place, and only foods which are emollient in their character are to be given. If great systemic disturbance and lowering of bodily heat have occurred, ice internally is contra-indicated, and heat is to be used externally. Thirst is best relieved by pieces of ice held in the mouth or by rinsing the mouth out with a little water. If the vomiting is persistent, it is to be treated as would be any case of hyperemesis,—by mustard plasters applied over the belly and to the feet, and by small doses of aconite and other gastric sedatives; or, if the vomiting seems to be centric in its origin, bromide of potassium may be given by the rectum in moderate amounts. Morphine and opium are not indicated, for the double reason that no particular benefit will accrue from their use and that they are apt to be harmful in children.

---

[1] Hæmoglobin cannot be tested for, as the gastric juice breaks it up into globulin and hæmin or hæmatin.

If the hemorrhage is severe enough to endanger life, transfusion is to be resorted to, using preferably a solution of common salt of the strength of seven per thousand of water, thoroughly clean and free from foreign bodies or undissolved masses. A much better solution, however, for transfusion is one composed of tribasic phosphate of lime and potassium chloride in the proportion of one hundred cubic centimetres of a saturated solution of the former to five cubic centimetres of a one-per-cent. solution of the latter. It should never be forgotten that transfusion is to be used as a last resort, and also that cases are on record in adults in which death has been produced by the rise in blood-pressure being followed by a free renewal of the hemorrhage.

DISPLACEMENTS OF THE STOMACH.

In childhood these displacements are, like the deformities, congenital. In some instances the stomach escapes through an opening in the diaphragm into the thorax. In other cases the diaphragm is entirely absent. Where there is entire transposition of the viscera the stomach is of course reversed also. Epstein[1] and Küchenmeister record such cases. While the latter displacements are very rare, the same thing cannot be said of those cases where the diaphragm has failed to keep the foreign viscus out of the thorax.

Thus, Holt[2] has recorded an instance in a two-year-old child where the stomach was found in the chest. Boyer[3] records an instance occurring in a five-year-old child, and Dimerbrock one in a child of seven. Schrandt[4] records an extraordinary case in a boy of fifteen years in which the hernia was complete.[1]

GASTRIC DEFORMITIES.

Gastric deformities present in childhood are nearly always congenital, the only other conditions being strictures and adhesions caused by corrosive poisons. Stenosis of the pylorus, of which we have already spoken, is a form of such malformation, of course, and we may also have pyloric incompetence. Where congenital constrictions exist, the viscus may be partitioned into sacculations. In some instances the stomach is a mere blind pouch connected by a fibrous cord to the duodenum, or else it is not connected with the intestine at all.

Musser[2] records a case of congenital "hour-glass contraction" of the stomach. The contraction took place in the centre, and was transverse; the peritoneum and submucous connective tissue were thickened at this point. Anterior to the constriction the muscular coat was hypertrophied.

GASTROMALACIA.

Synonyme.—Softening of the stomach.

Formerly it was supposed that the softened condition of the stomach found in some cases after death was an ante-mortem pathological change characteristic of a particular disease in the child. At present, however, this theory has been entirely set aside, and we know that the change is post-mortem in its production and depends on the action of the gastric juice on the surface of the stomach. In some instances the morbid change is limited to the mucous membrane; in others it extends through all the coats, so that a soft, irregular ulcer is formed, which perforates the viscus and allows the food to escape into the peritoneal cavity.

The morbid process most frequently affects the fundus, and, as the stomach is generally congested in this area, the whole appearance closely simulates that of active ante-mortem change. Though Welch[3] asserts very positively that the changes are altogether *after* death, yet Goodhart[4] believes that they may occur just prior to dissolution, being due at this time to defective gastric circulation, so that the walls are not supplied by alkaline fluid as they should be. Of course this state is really identical with the post-mortem change. Day,[5] writing so late as 1881, regards it as a true disease, but states candidly that he is unable to give any characteristic symptoms which would enable any one to diagnosticate the trouble before death. If the lesion is in any case ante-mortem it is, as Goodhart has well said, "the result of an ebbing life, not a disease which caused death."

THE DIARRHŒAL DISEASES,

ACUTE AND CHRONIC.

By L. EMMETT HOLT, M.D.

At the present time medical opinion is in somewhat of a transition stage in regard to the pathology of diarrhœal diseases. Many ancient fallacies have been exposed and dropped, but the building up of newer views upon surer foundations than those upon which the old rested is slow, and can scarcely be said to be much more than begun. We know enough to know that micro-organisms play an important part in these diseases, but which ones, and how, are still to a large degree unsolved problems. I have endeavored to look at diarrhœal diseases in the light of present knowledge, but not to go further than the state of knowledge would seem to warrant.

The difficulty in classifying these cases is at present very great, and the classification here offered has many points which are open to criticism, but it seems to satisfy present needs better than any other. One who sees autopsies upon his cases of intestinal disease is continually struck with the fact that there is a great disproportion between the symptoms and the lesions, and that essentially the same symptoms may exist with quite a diversity of lesions. A classification, then, which is based entirely upon the pathological findings becomes complicated and needlessly confusing to the clinician. I have tried to solve the difficulty by introducing a general section upon pathological anatomy in which the different lesions are considered *seriatim*, and in the further discussion to make a classification upon a purely clinical basis. Accurate etiological classification can be reached only when this subject has been cleared up by experimental bacteriology.

The propriety of introducing a separate section upon Dysentery has been carefully considered, but the question has been decided in the negative, for the following reasons. The common view that in diarrhœa we have to do with lesions in the small intestine, while the lesions of dysentery are in the colon, is entirely overthrown by the post-mortem findings. The truth is that in by far the largest number of cases classed clinically as "diarrhœa" the principal lesions are found in the large intestine, while in the cases of so-called "dysentery" lesions are almost invariably found in the lower ileum as well as in the colon.

Ulceration, high temperature, blood and mucus in the stools, and even infection, are not peculiar to dysentery. Ulceration and even pseudo-membrane are found in cases which were clinically only diarrhœa; the same is true of high temperature. Blood may occur in a great variety of conditions, and mucus is common to almost every case of intestinal disease in some stage. Furthermore, the evidence is now pretty convincing in favor of the opinion that several varieties of diarrhœa are infectious. We have left, then, only tenesmus, with or without the appearance of blood and mucus in the stools, as separating dysentery from diarrhœa. This group of symptoms depends not upon the nature of the pathological process, but upon its seat; tenesmus, with painful expulsive efforts, occurring with inflammation involving the rectum and lower colon when it reaches a certain degree of intensity.

It has seemed to me, then, better to abandon the use of the term "dysentery" as signifying a special form of disease; while perhaps it is desirable to retain the terms "dysenteric symptoms" or "dysenteric stools" to characterize certain forms of colitis or entero-colitis in which the inflammatory process is principally in the lower fourth of the large intestine. With a clear understanding of just what is meant by the term, its retention in the nomenclature of intestinal diseases cannot be objected to.

Those who consult these articles to find formulæ will be disappointed. The day of composite prescriptions containing half a dozen different ingredients or more is fast passing away. The administration in diarrhœa of mixtures containing an opiate, an astringent, an alkali, a stimulant, an antiseptic, and a ferment (and many such are constantly employed) is not only unscientific, but also useless. In many of these time-honored formulæ their value depends upon a single ingredient, or at most two, the others being very often positively injurious.

The routine use of certain complicated formulæ because some writer has lauded them as "good for diarrhœa" cannot be too much condemned. Simple prescribing is everywhere desirable, especially so in children, and most of all in diseases of the gastro-intestinal tract, where unnecessary drug-giving is almost certain to do harm.

I. GENERAL ETIOLOGY OF DIARRHŒAL DISEASES.

Age.—Statistics upon this point will vary somewhat according to the source from which they are taken. Those from large foundling asylums show the greatest frequency among children who are under six months of age. The following figures are from my own service in the children's class of the Northwestern Dispensary, and include those applying for treatment for diarrhœal diseases during five years, classified according to age:

First six months	119 cases.
Second six months	237 "
Third six months	149 "
Fourth six months	125 cases.
Over two years	142 "
Total	772 "

The mortality-records of the New York Infant Asylum give almost identical proportions for the different periods. In this institution the infants are, as a rule, nursed by the mothers. The children are born in the asylum, and the majority remain until they are two years old. These figures, then, may be taken to represent fairly the relative frequency of diarrhœal diseases at the different ages everywhere except in foundling asylums. They show a much greater susceptibility between the ages of six and eighteen months, and confirm the popular impression as to the dangers of the "second summer." These facts are, however, to be taken in connection with those regarding diet.

Surroundings.—While diarrhœal diseases are relatively more frequent in the city than in the country, and more frequent among the poor than among the well-to-do, still we cannot say that they are essentially diseases of the city, or of poverty. We meet with plenty of severe and even fatal cases among the rich and in the country, both at the sea-side and in the mountains. Although some experiments of Tompkins,[1] in Leicester, England, seem to show that bacteria are very much more numerous in the air in districts where diarrhœal diseases are prevalent, we have not yet accumulated sufficient evidence to establish the fact that there is a direct connection between a polluted atmosphere and their prevalence. Nor has any relation to bad sewerage been proved. They are not essentially filth-diseases, yet their frequency and severity are both increased by want of cleanliness in apartments, in the persons and clothing of infants, especially the diapers, chiefly, it appears, as these lead to a contamination of the food. Vacher[2] has shown that diarrhœa-mortality in the large English towns had no constant relation to the density of population.

In regard to dwellings, Meinert,[3] who investigated five hundred cases in Dresden, found the highest mortality among those living on ground-floors, which he suggests is due to greater heat here and atmospheric stagnation. Baginsky,[4] however, found in Berlin the highest mortality among those dwelling in basements.

Poverty, want of care, close and ill-ventilated rooms, predispose to diarrhœal diseases in summer, just as they do to pneumonia and bronchitis in winter, but it is doubtful if they do so to any greater degree. The predisposition in both cases is general and constitutional.

Constitution.—While it cannot be said that any special vice of constitution predisposes to these diseases, everything which lowers the general vitality increases the liability. In every large city there are seen congregated in its asylums or scattered among its tenement-population a great number of infants who are "born to die." They are swept off every summer in immense numbers by intestinal diseases, in winter by pneumonia. In every epidemic of diphtheria or scarlet fever they make up a large majority of the fatal cases. Those who treat diarrhœal diseases only in the country or among the better classes can but faintly appreciate the importance of this constitutional factor. These are the cases which must die, no matter where treated or how.

Children who suffer from athrepsia, syphilis, rickets, or tuberculosis are especially prone to be affected; likewise those with pneumonia, measles, diphtheria, and particularly pertussis.

Dentition.—There are a certain number of cases in which diarrhœa and dentition are associated, and where a pretty close connection between the two seems to exist, for the bowels quickly become normal when the teeth have pierced the gum. Such cases are rare, yet they do occur. Too much, however, cannot be said in contradiction of the wide-spread belief among the laity, that diarrhœa occurring with dentition is normal and even beneficial. Such a view costs many lives every year.

The immunity from diarrhœal diseases during dentition in the cold season is the best argument against the importance of this as an etiological factor. It is certainly a very minor consideration.

Diet and Feeding.—Of 1000 fatal cases recorded by Hope,[5] 30 had the breast exclusively; of 602 fatal cases recorded by Meinert, 24; and of 341 fatal cases recorded by Ballard,[6] 7: making a total of 1943 fatal cases, of which 61, or about 3 per cent., had the breast exclusively.

These facts speak volumes. They show that the manner of feeding is one of the most important factors in the production of diarrhœa. These facts are to be connected with those cited with reference to age. The poor in New York nurse their infants, as a rule, for about six months. If nursing is continued longer it is with the addition of other food, which is very often of the most indigestible kind and totally unfitted for infants. We find here incidental evidence bearing upon the same point as the figures of Hope and the others. As long as children are nursed entirely they suffer but little from diarrhœal diseases, but, in the same class of children, as soon as the age is reached when other food is added we find a very marked increase in this frequency. Children among the poor in tenements enjoy immunity from intestinal disease just in proportion as they are nursed at the breast, and just so long as they are so, but as soon as artificial feeding is begun diarrhœal diseases begin to be prevalent.

Why is it that artificial feeding among all classes, but among the poorer classes especially, is so dangerous? One of the oldest reasons assigned was the chemical composition of cow's milk, its indigestible casein, cow's milk being the almost universal substitute for the breast. To this subject much attention has been given, and, as Baruch[7] very well points out, all the refinements in the chemical analysis of milk have not brought us one step nearer the practical solution of the problem. Children continue to thrive upon it in winter and to get diarrhœa in the summer, dilute, sweeten, or change it as we may. Its safety in winter and in the country shows conclusively that the chemical composition of the milk is not an important factor, if indeed it plays any part.

Again, the manner in which hand-feeding is done has been blamed, and justly so. Hand-fed children are almost always overfed. It is a common practice among the poor for a large bottle supplied with a long nursing-tube to be filled and put beside the infant in its crib, allowing it to eat or sleep just as it likes; sleeping often for hours with the nipple in its mouth, or, more frequently, waking every few minutes for a few pulls at the bottle. Frequent feeding night and day, or rather this almost constant feeding, together with overfeeding, is in itself productive of great harm, even where the food given is all that it should be.

Articles of food unsuited to the child's age are often given. The practice of feeding infants only a few months old with "a taste from the table" is a common one among the poorer classes. Before an infant is a year old, potatoes, tea and coffee, beer, stews, sausage, and many other things equally indigestible, are given as a regular thing. Children at eighteen months often get only the regular diet of the family.

Almost all the diarrhœal attacks after the age of two years can be traced directly to improper food. The excessive use of starchy foods in early infancy is believed by many writers to be an important cause of diarrhœa. I think this point has been somewhat exaggerated.

The foregoing factors—overfeeding, irregular feeding, too frequent feeding, and the habitual use of improper articles of food—all unite in producing chronic infantile indigestion, and this chronic dyspepsia is more important than all other factors as a predisposing cause of diarrhœal diseases.

In nursing children diarrhœa is caused rarely by drugs given to the mother, or by dietetic errors on her part; frequently by menstruation or pregnancy, or by nervous influences, such as grief, exhaustion, etc.; sometimes by anæmia.

Impure cow's milk is an important cause. It may be due to disease in the cow, to the care and food of the cow, to adulteration or pollution of milk in the process of transportation and delivery, to dirty utensils, pails, pans, or cans in which the milk is kept, or to dirty bottles from which it is fed.

Almost all these changes are believed to depend upon the entrance of bacteria and their growth, and they will be more fully discussed in the next section.

The readiness with which impure cow's milk causes diarrhœa may be seen from the following circumstance. In the New York Infant Asylum on one occasion every one of twenty-three healthy children occupying one ward, all over two years of age, was attacked with diarrhœa in a single day. On investigation the cause was traced to the milk.

Contagion.—Hope,[8] investigating six hundred and thirty-four fatal cases, found that in sixty per cent. of the families "other cases of diarrhœa, more or less severe and generally among children," existed. In very many of these, of course, a common exciting cause is very probable, since the food, the manner of feeding, surroundings, etc., would be the same or similar in all the young children of a family. Lesage[9] has recorded the following experience. In a certain ward there were during the month of October no cases of diarrhœa. At the end of the month a case of "green diarrhœa" was admitted, and within six days eight other cases developed, six of these being in hand-fed children. In most small epidemics we have many cases developing simultaneously rather than successively, and this suggests a common origin for all.

Many such instances must be collated and studied before we can consider the contagion of certain forms of diarrhœal diseases as an established fact; but we know enough about the spread of typhoid fever and cholera from the poison of the discharges to make it our duty to insist upon the most careful disinfection of napkins and stools, particularly in summer. (See Prophylaxis.)

Foreign Bodies.—These may be ingested as food, such as partially-cooked rice or other cereals, dried fruits, raisins or currants, chunks of meat, raw vegetables, celery, radishes, etc., and green fruits. As these are not capable of digestion by the infant's organs, they act as foreign bodies.

One severe and nearly fatal case is known to me, in which the cause was the swallowing of a quantity of hair which the infant had pulled from a rug upon which it was accustomed to sit. The case lasted nearly three months. Finally a large mass of hair was passed by the bowels. Improvement began immediately, and the case went on to a rapid recovery. Such instances are extremely rare.

Exposure to Cold.—There seems still to be some good ground left for the belief that certain cases of diarrhœa, particularly in very young children, do depend upon cold and exposure. Their number is certainly not large, and they are apparently reflex in character.

Change of Air and Water.—It is extremely doubtful if a simple change of air or water alone will induce diarrhœa if no other factors are present. The cases usually attributed to such causes are more frequently due to dietetic errors or impure food.

Weaning.—This is almost certain to be followed by an attack of diarrhœa if it is done suddenly and in summer. There is nothing peculiar in "diarrhœa ablactatorum." The same causes are operative here as in all other cases of hand-feeding.

Telluric and Atmospheric Conditions.—Certain telluric conditions, the fluctuations of "ground-water," and the temperature of the soil, have been studied by Baginsky. The variations in the former had no relation to diarrhœa, while there was a pretty close relation between the earth-tempera-

ture and diarrhœa. This earth-temperature depends upon the atmospheric temperature, and it is the latter which he regards as the essential factor.

Ballard,[10] however, concludes, from his observations, that summer rise in diarrhœa does not begin until the earth-temperature at the depth of four feet reaches 56° F., no matter what the height reached at the depth of one foot or in the atmosphere may be; and that it continues without abatement until the temperature at the depth of four feet falls below the degree indicated, whatever the fluctuations or decline in the temperature of the atmosphere.

Tompkins,[1] from observations in the same town (Leicester, England), reaches the opinion that it is the temperature of the earth as recorded by the one-foot thermometer that is the essential one.

With these conflicting opinions, it does not seem that we are yet justified in the conclusion that the rise in frequency and mortality of diarrhœa in summer is in any special or direct way associated with earth-temperatures.

The relation of the different atmospheric conditions to diarrhœa has been the subject of very careful investigation by Seibert[11] of New York, Baginsky of Berlin, and Meinert of Dresden. The unanimous conclusion reached independently by the different observers is that neither barometric pressure, humidity, nor rainfall has any influence whatever upon the prevalence of or the mortality from infantile diarrhœa.

Dr. Seibert found also that in New York neither the direction nor the velocity of the wind had any relation to diarrhœa. Meinert reached a different conclusion upon the second point,—viz., that the highest mortality was with the least wind.

Temperature, then, is the only atmospheric condition which has been found by all observers to be at all closely associated with the prevalence of and mortality from diarrhœal diseases in children.

Chart I., from Seibert, shows the number of cases occurring in one of the large city dispensaries for ten years by months, as compared with the mean temperature for those months; and Chart II., from the same writer, shows the mortality in the city of New York for the same time from diarrhœal diseases in children under five years. These charts, which are almost identical, show, as Dr. Seibert very justly says, that with large figures there is an exact correspondence between the prevalence of these diseases and their mortality.

Chart III. is taken from Baginsky, and exhibits the relation between average temperature and the mortality from diarrhœal diseases among children in the city of Berlin. Chart IV. has been constructed from tables of statistics from the city of Baltimore published by Miller,[12] but covers the six warm months only.

These charts have a remarkably close resemblance to one another; and, taken as they are from widely different points, they may be regarded as showing pretty conclusively the facts regarding mean temperature and mortality from diarrhœal disease.

The charts show a slight rise in the mortality-curve in the month of May, a more marked one in June, and an enormous one in July; a sharp decline again in August, and a gradual one in September and October. During the latter month it reaches the point from which it rose in May.

In comparing these charts it will be seen that the month of May, with an average temperature in New York of 54° F. (12.2° C.) and in Berlin of 55.4° F. (13° C.), has but a little higher mortality than the winter months. In June, with an average temperature of about 61° F. (16° C.), we see a very great increase in the mortality; in New York it is nearly seven times greater than in May.

Vacher states that in London, whose average summer temperature is 59.6° F., every year for the last twenty-five when the death-rate from summer diarrhœa has exceeded three per thousand per annum the average summer temperature has exceeded 60° F. Again, during the same period in five years the annual mortality from this cause was less than two per thousand. These years gave an average temperature of 58.2° F.

We conclude, then, that there is required, for diarrhœal disease to become epidemic, a certain elevation of temperature, and that this temperature is but a little below 60° F. When near this critical point a difference of only one or two degrees has a very marked influence in increasing the amount of diarrhœa.

In every one of the charts the greatest mortality occurs in July, the month with the highest mean temperature. It is, however, seen that whereas the mean temperature of July exceeds that of June by only 4° or 5° F., the mortality in New York and Baltimore is about three times as great, and in Berlin twice as great. A similar statement can be made with reference to August as compared with July: here the difference in temperature is even less. The natural inference would seem to be that when a certain height of temperature has been reached a rise of a few degrees more leads to an enormous increase in the death-rate; and, further, that the mortality varies directly as the atmospheric heat.

Dr. Seibert, however, has very well pointed out the fallacy to which monthly averages may lead. He has studied every summer month for the ten years separately, as to its maximum and its minimum temperature, and the relation of these to the prevalence and mortality of diarrhœa. These observations show that there is no constant and close connection between the height of the temperature and the amount of diarrhœa: *e.g.*, July, 1879, and July, 1880, had practically the same temperature, and yet the former month showed twice as many cases of diarrhœa. "July, 1887, had eighteen days in which the temperature reached 85° F. and twelve in which it was over 90° F., and yet the number of cases was less than the average for July, and one-third less than July, 1882, which showed only fifteen hot days." "July, 1878, with fourteen hot days, had ninety-nine cases, while July, 1884, with only four hot days, had two hundred and sixty-six." We are, then, forced to the conclusion that there is no constant relation

between the degree of heat and the amount of diarrhœa; and consequently we cannot look upon heat as the direct agent which produces diarrhœa.

The same conclusion is sustained by two other facts. Meinert has shown that, in the continental cities of Europe, as we pass from north to south we find the death-rate from infantile diarrhœa *steadily decreasing.* He attributes the difference to the more general practice of maternal nursing in the southern cities, and to their open houses and out-of-door life. The second point is that if the direct effect of heat on the body were the chief cause we ought to find those most affected who would naturally be most susceptible to heat,—viz., the youngest infants. By referring to the figures cited under "Age" it will be seen that infants of the first period of six months suffered less than those of the second six, or even of the third. All the statistics of the relation of manner of feeding to mortality show that it is not because infants are very young, but because they are artificially fed, that they get diarrhœa.

How is the great difference between the mortality-records of June, July, and August to be explained?

All observations show that a succession of several warm days is necessary before the effect is seen in an increased amount of diarrhœa. As our first warm weather in New York rarely comes early in June, it is not until towards the end of the month that the mortality-rate of midsummer begins to appear.

Again, the susceptibility of the children in June is less, since they have just enjoyed the pleasant spring season, and are in comparatively good condition. It is not surprising, then, to find a much higher death-rate in July than in June.

In comparing July with August we find two months of nearly the same average temperature yet with widely different mortality-records. August gives a much smaller number, in spite of the fact that the children have just come through the hottest month of summer. The only reasonable explanation is that there are every summer in the community certain children who by their constitutional condition, their surroundings, and the way in which they are fed are predisposed to diarrhœa. The first hot month, July, sweeps off the largest number of them. I believe this to be the explanation of the relations of the mortality-figures of June, July, and August.

After a certain height of temperature is reached, all the conditions are present for the prevalence of diarrhœa, and increase beyond this point has no constant relation to the amount of diarrhœa. Diarrhœa begins to be common as soon as the average temperature reaches 60° F. It becomes very prevalent whenever the *minimum* temperature does not fall below 60° F.

Is the old idea of the direct action of heat or thermic fever as a cause of diarrhœa to be entirely set aside? Enough evidence has been brought forward already, I think, to show that this is at least not the most important action of heat. Still, I cannot resist the conclusion that a certain amount of depression does occur in the case of young infants when we have several days of excessive summer heat. This increases perspiration and consequently causes thirst. Thirst, even in nursing infants, may lead to their taking too much food; and still more is it likely in the case of hand-fed children, where the supply of food is not limited. Again, heat may depress the nervous system and in this way interfere with digestion. Often we see a combination of all these factors. They certainly are sufficient to create a strong predisposition to a diarrhœal attack.

Summary of Etiology.—The predisposition to diarrhœal diseases is furnished by age (under two years), enfeebled constitution, bad hygienic surroundings, and a chronic disorder of digestion depending upon improper methods of feeding or nursing and the habitual use of improper foods.

Their chief exciting cause is something to the development of which two things have a fixed and constant relation,—viz., a certain degree of atmospheric heat and the practice of artificial feeding. Both these conditions are necessary. We believe the chief causative factor to be bacteria, and that these act in most cases by inducing changes in the food.

II. THE RELATION OF BACTERIA TO DIARRHŒAL DISEASES.

I. THE EVIDENCE THAT THESE DISEASES DEPEND UPON BACTERIA AS THEIR PRINCIPAL EXCITING CAUSE.

This is in part deducible from a study of their etiology, partly from their clinical history, partly from pathological findings, and partly from analogy; but little, unfortunately, from purely experimental sources.

These diseases begin to prevail epidemically when a certain atmospheric temperature is reached,—an average of 58° to 60° F., there being with temperature below this point not many more deaths than in winter. This temperature, then, is an essential causative factor, and is that at which putrefactive processes first become very active.

The diarrhœal diseases are frequent and severe where other conditions favorable to bacterial growth, besides temperature, are present to a marked degree. They are found in the crowded tenement districts of the large cities, and in those places where the least attention is paid to cleanliness in milk foods, bottles, etc.

The prevalence of diarrhœa is coincident with the extent to which artificial feeding is carried on. Cow's milk is the food, to a greater or less degree, of all hand-fed infants, and it is an excellent culture medium for bacteria. By the present methods of handling cow's milk bacteria in the air find ready access to it, and living bacteria are, furthermore, always found in milk, in summer in great numbers. Finally, at this season milk is often allowed to remain for hours at a temperature high enough for very active bacterial development.

Abundant experience has shown that impure milk will produce diarrhœal diseases, and that these prevail among infants pretty much in the proportion in which such milk constitutes their food.

They are not frequent where infants get a food free from germs, such as breast-milk, even though the other conditions, hygienic and atmospheric, may be very unfavorable.

They are not frequent among infants in the country, who get for their food fresh cow's milk, nor among city children in winter,—which shows conclusively that it is not the chemical composition of cow's milk that is the difficulty.

Clinically we are brought face to face with a group of symptoms which admit of no other satisfactory explanation, in the light of our present knowledge, than that they are of toxic origin from the absorption from the intestines of ptomaines produced by bacteria. These symptoms are—high temperatures which autopsies show are not inflammatory; profound nervous symptoms, such as great prostration, delirium, coma, or convulsions, without, in most of the cases, any demonstrable changes in the brain, and often subsiding when the intestinal contents have been discharged; and, finally, the great evolution of offensive intestinal gases seen in nearly all acute cases.

It has been established that at least two forms of bacteria are capable of producing lesions in the intestines bearing some resemblance to those found in certain inflammatory diarrhœas of infancy,—viz., the bacillus of typhoid fever and the bacillus tuberculosis. Further, it is established that epidemic cholera, a disease most closely allied clinically with cholera infantum, is due to the comma bacillus.

Brieger has pointed out the poisonous nature of many of the ptomaines, which has been confirmed by the subsequent investigations of Bouchard and others. Vaughan[13] has isolated from milk, which had been fed to a child in whom cholera infantum developed, a ptomaine which produced vomiting and purging in a cat to which it was administered. He further found a similar substance in ice-cream which had produced in adults poisonous symptoms, prominent among which were vomiting and purging.

Other isolated instances are recorded in which poisonous ptomaines producing diarrhœa have been demonstrated in milk.[14] There is yet wanting sufficient evidence to establish the fact that any form of bacteria thus far investigated bears a causative relation to any of the varieties of diarrhœal disease in children.

We do not know yet what the bacteria are which produce these diseases; but the foregoing points taken together form a chain of evidence establishing, almost beyond the possibility of doubt, the fact that bacteria play a very important part in the production of a very large proportion of them.

We do not know positively by what avenue the bacteria gain access to the body, but the very close connection with the use of milk foods leads to the presumption that in the vast majority of cases it is through the food; although it is quite possible that in some cases the germs may be in the air, or even in the water.

II. THE RELATION OF BACTERIA TO THE OTHER ETIOLOGICAL FACTORS.

The study of intestinal bacteriology has already advanced far enough to establish the fact that micro-organisms are always present in the intestinal canal after the first twenty-four hours of life. Although the number present is very large, yet the varieties are few,—Escherich [15] having found but two species constantly occurring in the intestines of healthy nursing infants. This small number is explained by him by the conditions there existing,—viz., the exclusive diet, the absence of oxygen, and the fact that casein and milk-sugar are so rapidly and so completely absorbed. It is not due to the presence of bile, since bile is not an intestinal antiseptic, as we were formerly taught, Booker and others having found that almost all intestinal bacteria grow well in a ten-per-cent. solution of bile. Its influence in diminishing intestinal putrefaction, then, must be due to its action in digestion and absorption. When bile is absent both these processes are imperfect and decomposition takes place in the unabsorbed residue.

The acidity of the stomach does not protect the intestines against the entrance of living bacteria. Miller[16] found that an acidity of 0.16 per cent. of hydrochloric acid was required to stop the growth of bacteria, and the acidity of the infant's stomach has been shown by the best experiments to be considerably less than this. Van Puteren[17] found in observations on eight infants that it was only 0.08 per cent. Finally, MacFadyen[18] demonstrated that in dogs, the acidity of whose stomachs is well known to be great, almost any variety of bacteria could be made to pass the stomach, provided large draughts of water were given at the same time.

It does not seem likely that the varieties which are constantly present kill out the others introduced and in this way stand guard to protect the intestine, although this view has been suggested.

Healthy digestion and perfect absorption are the great obstacles to the development of new varieties.

Although other bacteria are being introduced all the time, they fail to develop, because their number is small or the resistance of the tissues great or they do not find proper food.

This normal balance may be destroyed, first, by increasing the amount of unabsorbed residue in the intestines. (1) This may be because too much food has been taken, all the other conditions being normal. (2) The food may be proper as to quantity and character, but there is failure of the digestive powers. This may be habitual, from constitutional debility; it may be transient and sudden, as in the invasion of any acute disease; it may be the result of many nervous influences, of which the depression resulting from high atmospheric temperatures is certainly one. (3) Food is given which is so improper for infantile digestion that it is acted on but very slightly or not at all by the stomach, and passes almost unchanged into the intestines.

In all these cases the final result is the same,—*i.e.*, there exist in the intestine undigested or partially-digested masses, which at the temperature of the body readily undergo putrefaction, they furnishing a soil in which many new forms of bacteria may thrive. If the active cause is only a transient one, as soon as these decomposing masses have been eliminated, proper feeding and the re-establishment of healthy digestion soon restore normal conditions.

If the cause continues operative, anatomical changes follow, which will be detailed hereafter.

The normal balance may be destroyed, in the second place, by the introduction of pathogenic germs. The effect of these germs will depend (1) upon their nature, (2) upon their number, (3) upon the vulnerability of the tissues. Regarding the nature of the germs which produce the injurious effects we know next to nothing: there are probably many varieties.

The toxic dose of bacteria must vary with each individual, and in the same individual it must be different under different circumstances. The number which can be taken into the intestine of a strong infant with healthy organs without any serious consequences is undoubtedly pretty large. A very much smaller number in a delicate infant of feeble constitution is sufficient to set up the most active decomposition, with very serious results.

The most important condition, however, is that of the digestive organs. While healthy organs are able to withstand the action of bacteria unless their number is very great, a mild intestinal catarrh, the result of habitual indigestion, and the presence of undigested materials, furnish the conditions the most favorable for their development. At such a time the entrance of a comparatively small number of bacteria may prove dangerous.

This subject of vulnerability of the tissues and dosage, if we may use the term, of bacteria throws a good deal of light upon certain commonly-observed facts in etiology,—as, for example, the immunity of children who have passed their second year. We may not explain this by their diet, for milk, and just as bad milk, is often given in the third year as in the first two years, yet without producing the same injurious results. We do not know of any anatomical or physiological differences in the intestinal tract in later childhood sufficient to explain this immunity, and we must conclude that, notwithstanding the continued introduction of bacteria in considerable numbers, comparative immunity exists because the intestinal tract almost ceases to be a vulnerable point for bacterial attack.

Children in the country and of the better classes suffer less, because their food contains fewer germs and their resistance is much greater.

Breast-fed children escape, for the reason that their digestive organs are usually healthy, and their food free from germs. Hand-fed children suffer most: first, because they are almost always over-fed; secondly, because a large number of them suffer almost all the time from a mild type of intestinal catarrh; and, thirdly, because their food in summer contains germs in large numbers. In the absence of the third condition, the two others are not usually potent enough to produce serious consequences. But the union of all three gives us our worst cases.

It is possible for ptomaines to be formed in the food outside the body and for symptoms to follow the ingestion of such food almost immediately, apart from any previously abnormal condition of the digestive tract, they requiring only absorption. Cases are occasionally met which present a clinical history suggesting such an explanation. But in the majority of cases we cannot tell whether the poisonous ptomaines are elaborated outside or inside the body or both, and really it makes but little difference.

III. THE RELATION OF BACTERIA TO THE LESIONS.

The continued presence of undigested or indigestible food in the intestines may produce effects mechanically, but more commonly, probably, by its decomposition by the agency of bacteria. These produce irritating acids and ptomaines, and gradually there is set up a low grade of intestinal catarrh. As a result of this catarrh, mucus and serum are added to the intestinal contents, and possibly also oxygen from the hyperæmia, all of these new conditions tending to increased activity of bacterial growth, which in turn aggravates the lesions. The lesions diminish or prevent the secretion of proper digestive fluids, and impaired power of digestion adds a new impulse to the decomposition. This condition may have been weeks or even months in developing, but when it exists it is easy to understand how pathogenic germs may develop with great rapidity which under normal conditions could not find a foothold.

Dr. T. M. Prudden[19] has shown, in his experiments upon rabbits with the streptococcus of diphtheria, that as much as a teaspoonful of a pure culture could be injected into the trachea of a healthy rabbit without producing pneumonia. The germs were found to have disappeared entirely when the animal was killed a few days later. If, however, before the introduction of the streptococci a certain amount of inflammation was excited by the inhalation of some irritant, as ammonia, the most intense pneumonia developed, and large colonies of streptococci were found in the exudation of the air-vesicles.

The law which these experiments illustrate is one of pretty wide application in bacteriology, and it has an important bearing upon the prevention of diarrhœal disease, under which head it will be referred to more fully.

That the symptoms of a mild intestinal disorder precede for some days the severe forms of diarrhœa is a matter of common clinical observation, and the experiments above referred to show how this fact is to be explained.

Exactly how the bacteria produce the lesions we cannot say positively.

At autopsies, where these are made within two or three hours after death, we find bacteria, as a rule, only upon the surface and in the superficial layers of the mucous membrane, even in cases where the lesions are the most severe; although they penetrate the tissues pretty rapidly after death, and at the end of eighteen to twenty-four hours may be found to have penetrated to the submucosa. In the worst cases the number of bacteria in the tissues is, as a rule, surprisingly few. Nor have I ever been able to demonstrate them in hardened specimens either of the mesenteric glands or of the kidneys: this might, however, possibly be done by cultures from fresh specimens.

The inference, however, is that it is not the bacteria directly which produce the lesions, but their ptomaines, and, further, that the action of the latter is principally upon the blood-vessels. That the lesion produced is in one case a catarrhal inflammation, in another croupous, in a third follicular (inflammation of the lymph-nodules), probably depends upon a difference in the form of bacteria.

In conclusion, we accept the doctrine that as an exciting cause in the intestinal disorders of infancy we are concerned most of all with the development of abnormal bacteria, but that before this takes place there is in almost all cases a failure of complete digestion and perfect absorption.

It seems to be possible for bacteria to be introduced in sufficient numbers to overpower even healthy digestive organs.

The anatomical changes are to be looked upon as secondary, and due to the continuance of the putrefactive processes.

III. PATHOLOGICAL ANATOMY.

In this section I shall confine myself almost entirely to a record of my personal observations.

I have made microscopical examinations of the intestines in one hundred and nine cases of infants and young children. Of this number seventy were cases of primary intestinal disease, the patients dying either from these diseases or from their complications. The remaining thirty-nine cases were divided as follows:

Pneumonia	14
Diphtheria	9
Tuberculosis	5
Athrepsia	6
Purpura	2
Empyema	1
Malignant pustule	1
Fracture of the skull	1
	39

These have been used principally as control cases, although in several of them interesting intestinal lesions of the milder types have been very often seen. In others were observed the results of diseases which had existed several months before. Of the autopsies upon the intestinal cases the greater part were taken consecutively in the New York Infant Asylum, where with very few exceptions every fatal case comes to the autopsy-table.[1] This fact adds some value to the observations from a statistical point of view. The cases of miscellaneous diseases were taken chiefly at random.

A few points in the anatomy of the normal intestine must be mentioned in order to an understanding of its pathological anatomy.

The intestinal wall is made up of four coats: the serous or peritoneal; the muscular, which is arranged in two layers, an internal circular and an external longitudinal; the submucous or cellular; and the mucous membrane. The submucous coat is made up of connective tissue, and contains the net-work of blood-vessels and lymph-channels. Between this and the mucosa is a thin layer of muscle-fibres, the muscularis mucosa, which also consists of two laminæ, the inner, circular one giving off numerous processes, which run between the tubular glands of Lieberkühn towards the surface of the mucosa. In the small intestine some of these enter the villi.

The mucosa is made up of tubular glands, or follicles of Lieberkühn, which are lined with cylindrical epithelium. Among these epithelial cells, irregularly placed, are certain large cells which are usually open towards the surface, their widest portion. These are the goblet- or beaker-cells, and it is now generally admitted that their function is the secretion of mucus. They are very much more numerous in the large than in the small intestine. Under the microscope they have a cloudy appearance, as their contents do not stain clearly. The tubular glands are connected with one another at their orifices by a continuous layer of cylindrical epithelium.

Between these glands the mucosa is made up almost entirely of lymphoid tissue, consisting of a reticulum, with a pretty abundant sprinkling of small round cells occupying the spaces. Scattered here and there are seen aggregations of lymphoid cells, forming the lymph-nodules or solitary follicles. Their internal structure is the same as that of similar nodules elsewhere in the body.

They are situated partly in the mucosa and partly in the submucosa. Those in the small intestine are almost entirely in the mucosa. They have no investing capsule, although in the submucosa a sort of limiting membrane is made up by the condensed connective tissue. In the mucosa they are covered at their summits by the epithelium only; laterally they are partly limited by the tubular glands, but the cells infiltrate more or less the adenoid tissue overlying the mass of the nodule.

---

[1] For valuable assistance in this portion of the work I wish here to express my indebtedness to Dr. T. Mitchell Prudden, Director of the Laboratory of the College of Physicians and Surgeons, and to Dr. John S. Thacher, Director of the Laboratory of the New York Polyclinic. I am indebted to Dr. Robert Milbank, my colleague at the Infant Asylum, for allowing me to make use of the cases in his service in the summer of 1888.

In the small intestine the solitary lymph-nodules are scarcely visible to the naked eye unless they are enlarged. In the colon in a normal state they are gray, almost flat, and present very often a central dot, which may be pigmentation or simply a slight depression. This was once regarded as the opening of an excretory duct.

The great frequency with which these lymph-nodules are enlarged in infants has led some to believe that these are always round and projecting. The routine examination of the intestines in all autopsies in children will quickly show that this is not the case. Peyer's patches are simply aggregations of a number of these lymph-nodules.

In addition to the larger nodules easily recognized under the microscope, there are seen in infants a considerable number of small collections of a few dozens of round cells, in the upper part of the submucosa, which might be mistaken for inflammatory products.

The structure of the villi and the distribution of blood-vessels present no peculiarities in early life.

The principal points of difference to be kept in mind in relation to pathology are the abundance of the lymph-nodules and smaller lymphoid masses and the richness of the lymphatic plexuses.

EXAMINATION OF THE INTESTINES.

All autopsies upon cases of intestinal disease should be made as early as possible. For microscopical study this is indispensable, but the gross changes are not often materially altered by a delay of twenty-four hours. The common practice of washing the intestines by allowing a stream of water to flow through them before they are opened is objectionable, since in this way there is no opportunity to study the contents of the bowel, a matter sometimes of much interest.

For microscopical work the part of intestine to be examined should be laid open carefully by scissors, and pieces cut off from one to two inches long; these should not be washed at all if the part is to be examined for bacteria, otherwise they may be waved back and forth a few times in a saline solution. They should be gently stretched enough to obliterate the deep folds in the mucosa if any exist, and dropped into a flat dish containing ninety-five-per-cent. alcohol. The specimen stiffens in a few minutes: the borders which have been handled can then be cut away and the specimens put into jars. For hardening, ninety-five-per-cent. alcohol should be continued if we wish to cut them in a few days; if they are to remain long, a weaker solution—eighty-per-cent.—is better, or they may become too hard and brittle. By using the strong alcohol and changing it once, specimens may be cut in four or five days. They are then to be embedded in celloidin in the usual manner, double-stained with hæmatoxylin and eosine, and mounted in balsam.

The rough handling which intestines have generally received at autopsy is responsible for some of the erroneous notions which exist concerning their pathology.

Post-Mortem Changes.—These occur probably more readily in the intestines than in any other mucous membrane in the body. Unless they have been carefully studied by themselves, they lead to continued confusion respecting the interpretation of the microscopical appearances.

The post-mortem changes in the mucous membrane depend upon the time that has elapsed after death before the autopsy is made, upon the nature of the intestinal contents, upon their reaction, upon the weather, upon whether the intestine is contracted or distended, upon the region from which the specimen is taken, and upon the care with which the organs are handled, as well as upon disease. Woodward[20] states that any observations upon the epithelium must be made within six hours to be significant, and that loss of epithelium after that time is not to be looked upon as evidence of disease. With this Nothnagel[21] has concurred, and since his time Baginsky.[4] My own experience leads me to practically the same conclusion, taking, however, the other circumstances mentioned as modifying influences. If the intestines are filled with thin fluid matters, the changes take place very much more rapidly than when they are empty or simply coated with mucus. The changes are more rapid if the contents are alkaline than if they are acid; more rapid in hot weather than in cold, unless all bodies are put immediately upon ice. Contracted portions of intestine are always better preserved than those that are distended. In fact, one must be very cautious in drawing any conclusions respecting the appearances of intestine which has been stretched by gaseous distention, since by this all the structures are much changed.

So far as region is concerned, in over eighty examinations in which the point was noted, the epithelium was lost in the jejunum in forty per cent. of the cases, in the ileum in sixty per cent., in the colon in sixty-four per cent. The difference seems to depend largely upon the difference in contents.

Careful handling makes a great difference. Diseased epithelium certainly loosens very much more readily than healthy epithelium, and even six hours after death its absence under circumstances favorable to maceration and decomposition is not always evidence that it was ante-mortem. On the other hand, I have seen epithelium almost perfect in the ileum of a case in which the autopsy was made sixty-eight hours after death.

Loosening and falling out of the tubular glands or follicles of Lieberkühn was seen to a greater or less degree in almost all specimens from autopsies over twenty-four hours old. Under favorable circumstances this may take place even in twelve hours. It is more rarely seen in contracted, but almost always in dilated, portions of the gut. This appearance, when it is general, is not unlike that seen in chronic inflammation with atrophy and disappearance of these structures. The sockets or beds from which the gland has fallen out are usually clearly defined in the former case. (See Fig. 1.)

Disappearance of these glands may lead to a great apparent increase in the number of cells in the mucosa.

The solitary lymph-nodules when enlarged often present, both to the naked eye and under the microscope, appearances entirely due to post-mortem change, which are almost identical with those seen in commencing ulceration. This consists in loss of their epithelial covering, and erosion of their summits. (See Photos. I. and II.* and Fig. 1.) This is common in autopsies which are more than twenty-four hours old.

In the small intestine the villi, when deprived of their epithelium, frequently fall over upon the surface of the mucous membrane, giving an appearance closely resembling that of a thick layer of round cells.

In autopsies made from thirty-six to sixty hours or more after death, the epithelium and other cells have often become so altered as to stain slowly, indistinctly, or not at all.

I have made some experiments upon healthy intestines, studying the changes of decomposition under different conditions, and have seen produced from this cause appearances which were scarcely distinguishable from those seen in many cases of acute inflammation of the intestine. The greatest discretion, then, must be exercised in drawing conclusions from these appearances, and all the modifying conditions must be taken into consideration.

Bacteria.—With reference to this subject we must be still more cautious in drawing any conclusions. Under the most favorable circumstances I have found experimentally that bacteria would penetrate a considerable distance into the mucosa in fourteen hours, while in twenty-six hours they were diffusely scattered through the whole mucosa, and in forty hours they were found everywhere in great numbers.

PATHOLOGICAL CLASSIFICATION.

As intimated in the introduction, it is not advisable in intestinal diseases to endeavor to make a clinical and a pathological classification exactly coincide. Such an attempt would lead rather to confusion and often to needless repetition. The subjoined classification is as simple a grouping of the cases as seems to be possible. There are included here only the seventy fatal cases of diarrhœal disease in which the exact nature of the changes was determined microscopically.

I.† *Acute desquamative catarrh*, embracing the acute cases with no lesions except loss of the superficial epithelial layer: twenty-two cases.

---

* These are reproductions from photographs taken for me by O. G. Mason, Photographic Department of Bellevue Hospital.

† The propriety of separating classes I. and II. may be questioned. We cannot be sure that the process in I. is not the first stage of II. Still, the fact that in so large a number of cases we find nothing but a loss of epithelium is a striking one, and, taken with the clinical history, seems to make it desirable to separate them from the cases where other lesions are found.

II. *Acute catarrhal inflammation*, other lesions than the loss of epithelium being present: sixteen cases.

III. *Acute inflammation of the lymph-nodules, with ulceration* (*follicular ulceration*): twenty cases.

IV. *Acute croupous inflammation:* nine cases.

V. *Chronic inflammation:* three cases.

I. **Acute Desquamative Catarrh**, or acute cases in which the only essential change is a loss of the superficial epithelium. Of these twenty-two cases, thirteen were children previously suffering from athrepsia; four were clinically cases of genuine cholera infantum; two were cases of acute dyspeptic catarrh occurring during convalescence in children who had suffered previously from acute catarrhal inflammation of the intestine; two were cases of rather marked gastritis, but lesions very much less marked in the intestine; and one was an acute dyspeptic diarrhœa in a six-weeks infant. It is to be regretted that only a small proportion of these autopsies were made within the six-hour limit previously laid down, so that we cannot affirm that the loss of epithelium was not a post-mortem change. It was found, however, absent, or nearly so, in cases examined as early as three hours after death, and the probabilities are in favor of the change being ante-mortem in most of the cases.

In one case in which marked diarrhœal symptoms had existed during life, complicating pneumonia, I obtained an examination of the intestines three hours after death. In this case the epithelium was almost perfect.

Desquamation of the superficial epithelium is not, therefore, a constant accompaniment of acute diarrhœa, but it probably occurs to a greater or less extent in most of the cases severe enough to cause death.

A noticeable feature is the large proportion of cases of athrepsia. It is surprising that these cases succumb so readily. In nearly all the symptoms were only those of an ordinary acute dyspeptic diarrhœa of no great severity. In these, as well as in the cases of cholera infantum, it is evident that the lesions found are not sufficient to explain the symptoms during life. The majority of these cases are of from two to four days' duration.

Gross Appearances.—In the cases which have presented clinically the symptoms of an acute dyspeptic diarrhœa, the small intestine is apt to be distended with gas, and to contain at its lower portion undigested food and thin yellow or dirty-green fluid or semi-fluid materials, often quite offensive; the large intestine is frequently empty, but may contain matters similar to those seen in the small intestine, mixed with mucus. Except for the contents, the appearance of the intestine in many of the cases does not differ essentially from that seen after death from any other disease. In athrepsia cases the effects of the long antecedent chronic dyspeptic catarrh are often seen in the shape of an enlargement of the solitary lymph-nodules of the colon, or more rarely pigmentation. There are irregular areas of congestion, but so are there in almost every intestine seen post mortem.

In the cases of cholera infantum the appearances are more characteristic.

The small intestine is apt to be distended with gas, as is also the transverse colon; the rest of the large intestine is generally contracted and nearly empty.

The intestinal contents consist quite uniformly of a fluid material of a grayish-white color and about the consistency of thin gruel. It has a mawkish odor, but not usually a very offensive one.

The mucous membrane of both small and large intestines has most commonly a pale, "washed-out" appearance. Less frequently this is seen in the small intestine only, while there are small areas of slight congestion in the colon.

The above appearances are those most commonly met with, and the only ones which are characteristic of the disease.

Since, however, choleriform diarrhœa is occasionally engrafted upon another pathological process in the intestines, we may find widely-varying appearances, depending upon the antecedent disorder, such as catarrhal inflammation of varying degrees, and not very infrequently old ulcerations.

Microscopical Appearances.—These, like the gross appearances, are usually disappointing. The changes are generally wide-spread, and frequently involve almost the whole alimentary tract. The small intestine usually suffers as much as the colon, and in a small proportion of the cases the major part of the lesion is in the small intestine.

In the most recent autopsies we find the superficial epithelium for the most part gone. Here and there a few cells may be seen *in situ.* The cells lining the tubular glands at their mouths have likewise largely disappeared. In the fundi they are usually present. The nuclei of the cells which remain stain normally, but the protoplasm is frequently cloudy and finely granular.

I have stained quite a number of these specimens for bacteria. The rule is, in examinations made early, to find them upon the surface only. As we have previously seen, the position in which they are found after five or six hours is of no positive significance. In the single case of cholera infantum in which I got an early autopsy I found the whole mucosa filled in places with small diplococci. A single case admits of no deductions.

II. **Acute Catarrhal Inflammation,** with lesions other than a loss of epithelium (sixteen cases, or twenty-three per cent. of the fatal cases). These cases are distinguished clinically from the foregoing by their longer course, the average duration being about a week, and usually by a continuous elevation of temperature,—101° to 104° F. In a few of these cases there was a slower course, with little or no fever after the onset. This course was more often seen in children who had previously suffered from athrepsia. The relative frequency of these cases is manifestly not represented by the number of autopsies, since the largest proportion of them terminate in recovery.

Gross Appearances.—As in all other varieties of intestinal inflammation, the lower ileum and the colon are the most frequently affected, but not so exclusively here. It is not uncommon to find changes of quite a marked character through a greater part of the small intestine. This is more frequently seen in the cases of short duration, where they are sometimes more marked than in the colon. In the cases of longer duration it is the colon which shows the most extensive changes, with few exceptions. It is extremely rare to find the small intestine the exclusive seat of disease.

The intestinal contents are usually green in color and thin. The mucous membrane is often coated with tenacious mucus. The small intestine is commonly distended with gas, the large intestine nearly empty, excepting the transverse colon, which is likewise distended. The mucous membrane is somewhat swollen, but this is not a marked feature. In the small intestine there are occasionally seen swelling and œdema of the villi so that they project abnormally and give a plush-like appearance; with a lens they look somewhat club-shaped. Congestion is a constant feature. It may be arborescent, following the course of the veins, which are seen to be greatly engorged: this occurs usually in the small intestine, and is scarcely pathological. It may be simply upon the folds into which the mucous membrane is thrown. It may be about the solitary lymph-nodules, forming a little red zone about the follicle; or it may be so intense that the whole intestine for a considerable space is of a uniform deep-red color. The last appearance is usually seen in scattered patches a few inches long, the intervening intestine often being nearly normal in color. These patches are very frequent in the cæcum and sigmoid flexure. Small hemorrhagic spots are often seen here and there widely scattered. In most of the cases there is no real thickening of the intestinal wall, but this is often simulated by the contraction of the muscular coats. In the few cases of great severity there is marked thickening and a general resemblance to the appearances of croupous inflammation: the distinction from the latter can usually be made by the microscope only.

The lymph-nodules (solitary follicles) may be normal in size, but they are more frequently swollen throughout the colon. They project above the mucous membrane, and appear about the size of a mustard-seed, sometimes larger. In the small intestine this enlargement is much less frequently seen, although when enlarged they project much more than in the colon.

Peyer's patches are swollen in but a very small proportion of the cases; when this swelling is recent, there is usually associated quite marked congestion of the patch. This is, however, not common. The swelling of the solitary lymph-nodules and Peyer's patches found at autopsy may depend not upon the final attack of diarrhœa, but upon antecedent disease. The existence of pigmentation favors the latter explanation, while acute congestion points to recent disease. In many cases it is impossible to say positively whether the swelling is recent or old.

Microscopical Appearances.—As has been previously stated, nothing can be affirmed concerning the condition of the epithelium unless the autopsies have been made within six hours (sooner in very hot weather), and the intestines carefully handled. (See paragraph upon post-mortem changes.) There is usually loss of the superficial epithelium and of that lining the tubular glands at their orifices, similar to what has been described in the first class of cases. Upon the surface of the mucosa and within the tubular glands fine granular matter is seen from the broken-down epithelium. The goblet-cells are distended with mucus, and do not stain clearly. The lumen of the tubular glands is narrowed from pressure due to the swelling of the adenoid tissue which separates them, which is partly from œdema and partly from cell-infiltration. (See Fig. 5.) Entire tubular glands may loosen and fall out, particularly where the intestine has been distended. In the small intestine the villi project normally in most cases, unless the part examined has been stretched by gaseous distention, when they may lie almost flat and simulate closely a very thick layer of new round cells. There is in most cases very little epithelium remaining where the other changes are marked.

It sometimes happens that a thick layer of mucus and round cells adheres closely to the surface, resembling very much a layer of pseudo-membrane. (See Fig. 6.) Beneath this we may find in places nearly normal epithelium.

In the milder forms of the lesion the amount of infiltration of round cells is not great, and is usually limited to the mucosa. It is more marked in the superficial than in the deeper parts: the extent depends principally upon the duration of the process. In the very severe cases we find a dense infiltration of the mucosa and of the submucosa also, in places quite to the muscular coat. These cases closely resemble those of the croupous variety, lacking only the pseudo-membrane.

Occasionally in the severe catarrhal variety, but more frequently in the croupous, there are seen superficial erosions of the mucosa or catarrhal ulcers. These do not appear at all to the naked eye. There is a complete destruction of more or less of the thickness of the mucosa, and only the fundi of the tubular glands may remain. It rarely goes to the muscularis mucosæ. These erosions never have sharp, well-defined borders, but the mucosa seems to be frayed out at these points. It appears to be a gradual process of softening, liquefaction, and removal of the superficial parts, adenoid tissue, and tubular glands, from the intensity of the inflammation. (See Fig. 7.)

The lymph-nodules are swollen to a greater or less degree, chiefly from an increase in the number of round cells in almost all the cases. In a number of the cases there have been seen at the centre of the nodules, mingled with the round lymphoid cells, collections of large epithelial cells of a peculiar character. They were seen both in recent cases and in those of longer standing. Sometimes there are catarrhal changes only, and sometimes the swelling of the lymph-nodules is the predominant feature of the lesion.

If the inflammatory process is sufficiently intense and prolonged, the lymph-nodules break down and ulcerate. These cases are considered elsewhere in this article. The appearances in Peyer's patches are similar to those seen in the solitary lymph-nodules, but are much less marked, and frequently are absent altogether.

The blood-vessels take an active part in this process. The small veins and capillaries of the submucosa and mucosa are gorged with blood. In the patches of intense congestion these dilated vessels occupy a large part of the field. Small extravasations are very common, and occasionally larger ones are seen. There are no essential changes in the muscular coats.

This variety, except in its very severe form, which is not very common, presents no changes that cannot readily be repaired. New epithelium forms with very great facility. The infiltration of cells quickly disappears by absorption; the most persistent change is usually the swelling of the lymph-nodules, which lasts a long time, and this appears to be an important factor in the tendency to relapses and recurring attacks. The inflammatory process is not likely to go on to a chronic one unless there is a continuance of the exciting cause or the patient's constitution is a bad one. The very severe forms are almost certainly fatal.

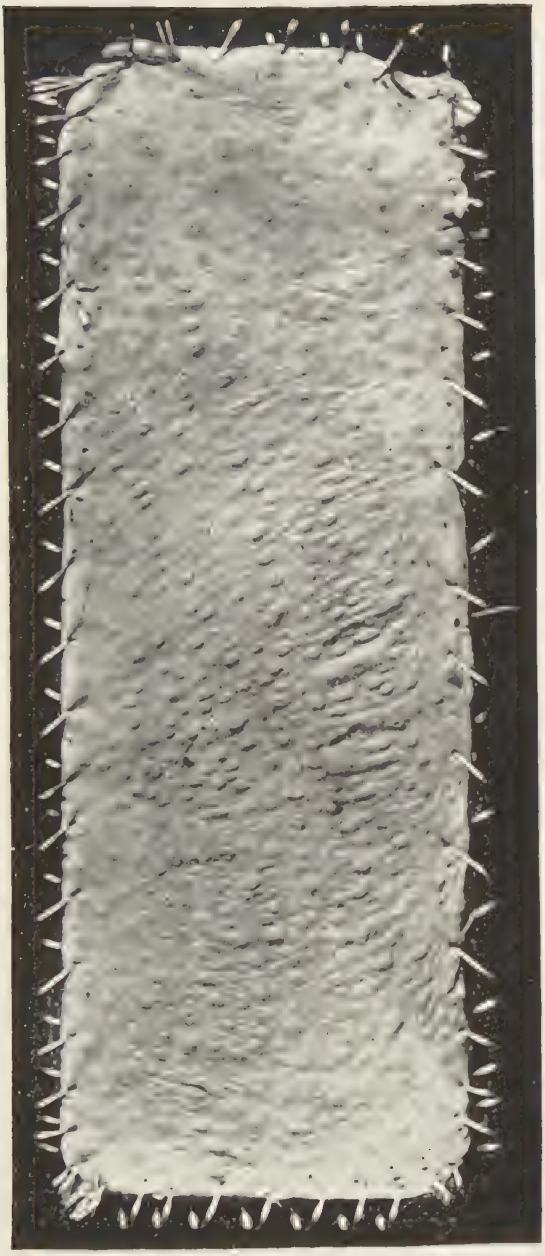
III. **Inflammation of the Lymph-Nodules, with Ulceration (Follicular Ulceration).**—The cases of acute inflammation of the lymph-nodules which do not terminate in ulceration are included with those of catarrhal inflammation. They embrace a very large proportion of the cases which recover.

Frequency.—Excluding cases of tuberculosis of the intestines, I have met with follicular ulcers in twenty out of seventy fatal cases, or in nearly one-third of the autopsies upon infants dying from diarrhœal diseases. They were never seen in cases which had lasted less than a week, and not commonly before the latter part of the second week, the average duration of the cases being about three weeks. In the fatal cases which had lasted more than two weeks the proportion of those with follicular ulceration was very much greater.

Clinically these cases run a slower course than the other varieties; the stomach is less frequently involved; there is not usually any marked continuous rise in temperature; blood in the stools is quite exceptional.

Gross Appearances.—Situation.—Of twenty cases in which follicular ulcers were found, they were in the small intestine alone in but two cases; in the small intestine and the colon in three cases; in the remainder they were situated only in the colon. When in the small intestine they were never seen except in the lower ileum. Occasionally ulceration is seen in one or two of the nodules of a Peyer's patch. Of those limited to the colon, there were ulcers in the whole extent in about one-half the cases; in the remainder they were in the lower half only. The deepest ulcers were seen in the order of frequency in the descending colon, the sigmoid flexure, the transverse colon, and the rectum. When ulcers were present throughout the colon, they were almost invariably smaller and more superficial in the upper than in the lower half.

Photo. I.



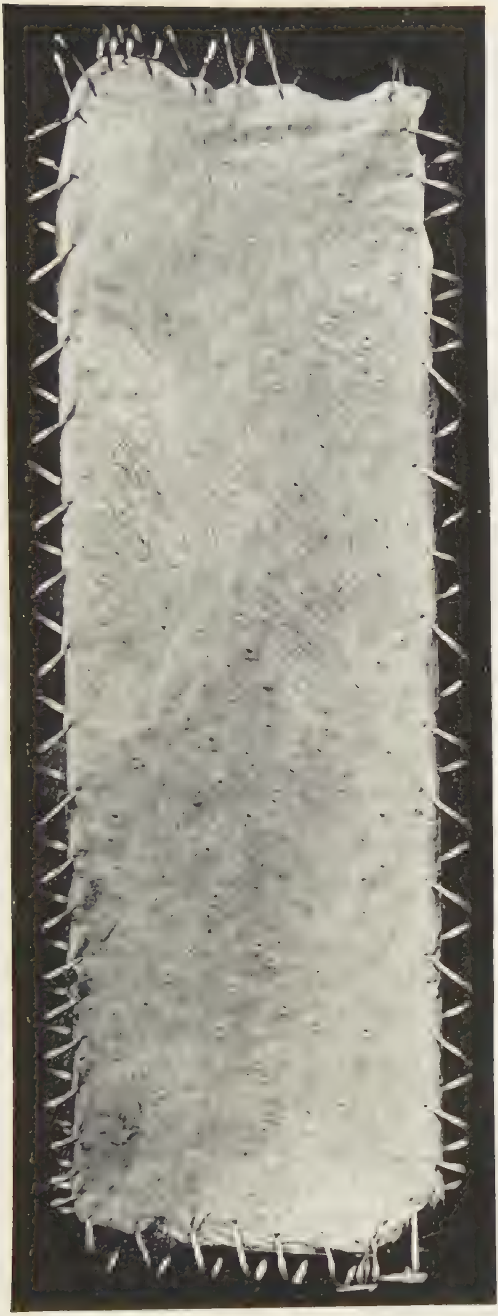
Hyperplasia of the Lymph-Nodules (Solitary Follicles) of the Colon.

History.—Never any acute diarrhœa; until five months old almost all stools were green or brown, and contained mucus; general health was not affected. Died of acute pneumonia, at ten months, without intestinal symptoms.

Autopsy.—Twenty-six hours. Very marked swelling of solitary lymph-nodules throughout colon. The picture gives a very accurate idea of the appearance.

For microscopical examination, compare Fig. 1.

Photo. II.

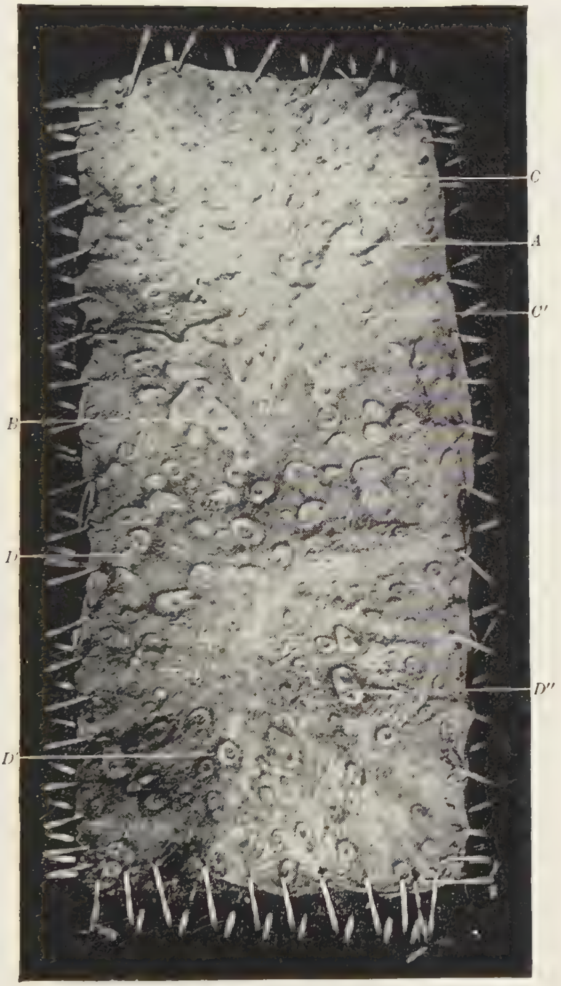


Enlarged Lymph-Nodules (Solitary Follicles) of the Colon.

The lymph-nodules are very much enlarged and project. They show a central pit or depression large enough to admit the point of a small probe. This appearance is due almost entirely to post-mortem changes, but resembles closely the beginning of follicular ulcers.

History.—From same case as Photo. I.

PHOTO. III.



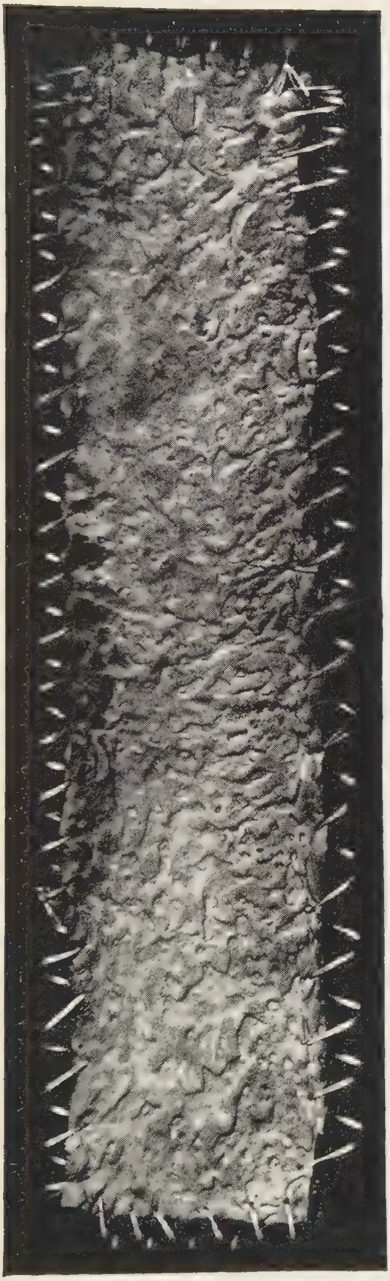
SUPERFICIAL ULCERS OF THE COLON.

History.—Nine months old; continuous intestinal symptoms fifteen days; temperature, 101° to 102° F.; stools green, yellow, mucous, and offensive.

Autopsy.—Twenty-five hours. Superficial ulcers throughout colon; no deep ulcers. Photo. is from descending colon. At the middle and lower portions of the specimen are small circular ulcers, as at *D* and *D′*. At the centre of each one a small projecting nodule is seen,—the solitary follicle. At *D″* two single ulcers have coalesced; at *B* five have coalesced, forming a shallow, irregular ulcer. The upper part of the specimen shows a very large ulcer, *C*, *C′*, about one and a half inches long and the width of the gut, evidently from a coalescence of many small ones. At *A* only is a small island of the mucosa seen. The small, granular bodies seen in the floor of the large ulcer are solitary lymph-nodules.

For microscopical appearances, compare Fig. 4.

Photo. IV.

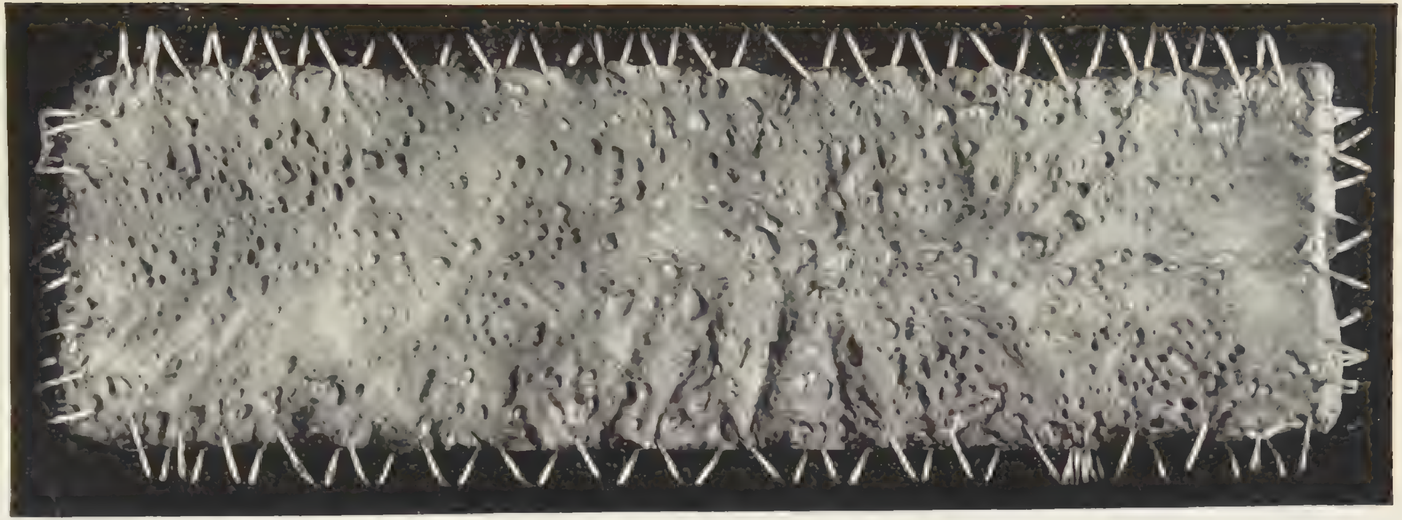


Superficial Ulcers of the Colon.

History.—Delicate, hand-fed child, two months old; ill two weeks; temperature, 99° to 103° F.; no blood in stools.

Autopsy.—Twenty-four hours. Catarrhal inflammation in lower ileum, but no ulcers. Whole colon involved, and closely resembled specimen shown in photograph. It is filled with irregular, worm-eaten ulcers, none of which go deeper than the mucous membrane. At the bottom of the ulcers small, projecting, seed-like bodies are seen,—the solitary follicles. The formation of these ulcers is similar to that shown in Photo. III.

PHOTO. V.



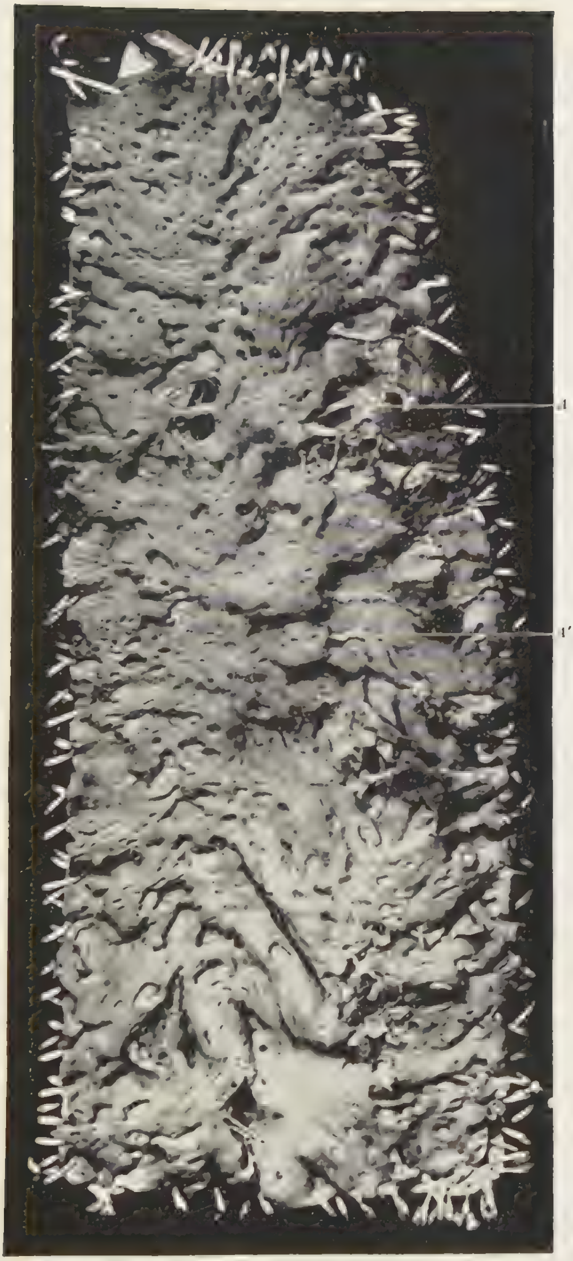
DEEP FOLLICULAR ULCERS OF THE COLON.

History.—Delicate child fourteen months old, sick twelve days with acute intestinal symptoms, stools green, yellow, brown, and watery, no blood; temperature usually 100° to 101° F.

Autopsy.—Nineteen hours. Small intestine normal. Ulcers throughout colon—in ascending small and circular, in transverse large and ragged. (See Photo. VI.) Specimen is from descending colon. It shows great numbers of small, round, punched-out ulcers, and a few larger ones about the middle from coalescence of several smaller ones. Nearly all the ulcers go to the muscular coat.

For microscopical appearances, compare Fig. 3.

PHOTO. VI.

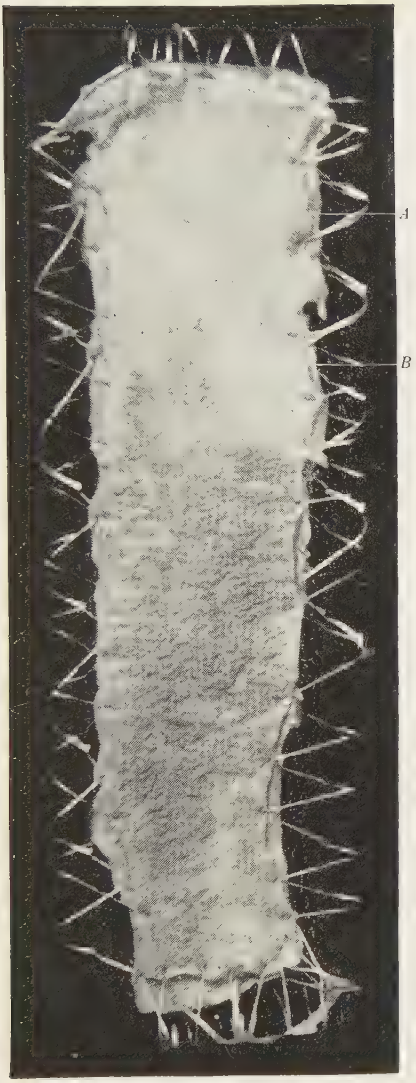


DEEP SLOUGHING ULCERS OF THE COLON.

From same case as Photo. V. The specimen here shown is the transverse colon. Large ragged ulcers are seen, with sloughs hanging from their surface. Where sloughs have separated, at *A* and *A′*, the transverse striations of the circular muscular coat are plainly seen. No perforations were present. Many small, circular ulcers are seen, resembling the smallest in Photo. V.

The microscope showed no fibrin in the exudation.

PHOTO. VII.



CROUPOUS INFLAMMATION OF THE ILEUM.

History.—Delicate child, eleven months old; mild diarrhœa two weeks; without fever; acute, severe symptoms twelve days; temperature, 100° to 102.5° F.; stools green, mucous, no blood.

Autopsy.—Twenty-three hours. Pulmonary tuberculosis. Lesions of intestine involve last foot of ileum and whole colon. The photograph is of a specimen from the lower ileum, and shows the abrupt termination of the lesion. The upper half of the specimen shows normal small intestine, Peyer's patches being seen at *A* and *B*. The lower half shows intense inflammatory changes. The intestine here was much thickened, intensely congested, and the surface had a rough, granular appearance, which is very well shown. No pseudo-membrane could be seen by the naked eye, but the microscope showed quite an abundant fibrinous layer upon the surface.

The microscopical appearances resembled those of Fig. 9.

In the early stage these ulcers appear as tiny excavations at the summit of the prominent, projecting lymph-nodule (solitary follicle). This pit-like depression admits a fine probe. An exactly similar appearance is seen as a result of post-mortem changes in late autopsies in intestines where there has been nothing but hyperplasia of the nodules during life. (See Photos. I. and II.)

Later the whole nodule may be destroyed by ulceration, leaving a small deep ulcer about one-twelfth of an inch in diameter reaching into the submucosa, its orifice being somewhat narrowed. Finally the ulcer extends in the submucosa, undermining the mucosa, which perishes as its nutrition is cut off. The usual size of the fully-formed ulcers is from one-twelfth to one-fourth of an inch. (See Photo. V.) By the coalescence of several of these in the manner just indicated, extensive ulcers, an inch or more in diameter, sometimes form. At the bottom of these larger ulcers the transverse striæ of the circular muscular coat are often plainly seen. (See Photo. VI.) It is exceedingly doubtful if perforation ever occurs in children from these ulcers. They have always overhanging, never bevelled, edges; the smaller ones are circular, and when closely set give the intestine a sieve-like appearance.

There is another variety of ulcers which differs in some marked features from those just described, but, as the starting-point seems to be the lymph-nodules (solitary follicles), I have included them with the follicular ulcers. I have seen but three well-marked cases.

These ulcers are superficial, never involving anything but the mucosa. They are at first small, and consist in a destruction of the mucosa immediately overlying the solitary follicle. When a little larger they are circular, and show in the centre a small, slightly-projecting, seed-like body, which is the follicle. Deep ulceration of the follicle does not occur, yet the ulcers readily coalesce and form large ones, sometimes two or three inches wide. But even these large ulcers do not go deeper than the mucosa. Ulcers identical with the smaller ones I have several times seen in the ascending colon when the common deep follicular ulcers existed in the lower portion of the large intestine. This fact and the entire absence of fibrin have led me to class these broad superficial ulcers with the follicular ones, rather than as croupous, although they have some features which suggest the latter origin.

Photo. V. is a typical illustration of the deep ulcers, both as to size and distribution. Photo. VI. shows large undermining ulcers which have had their beginning in deep follicular ulcers. More or less sloughing has occurred in this case. This is the only instance of extensive sloughing I have met with.

Both varieties of the superficial ulcers are shown in Photo. III.

In Photo. IV. the same process of superficial ulceration about the solitary lymph-follicles is seen, giving the mucous membrane a peculiar worm-eaten appearance. Closer examination shows in these specimens at the centre or at the bottom of the ulcers a small seed-like body, which is the lymph-nodule.

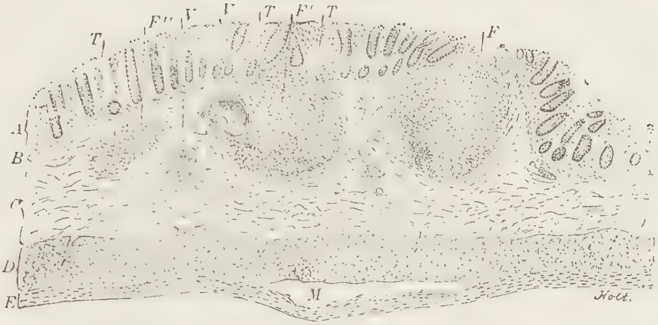
Microscopical Appearances.—The lymph-nodules swell, principally from the accumulation within them of round cells. In some of the cases epithelioid cells are also seen. This swelling causes an elevation of the whole mucosa at the point where it overlies the nodule. (Figs. 1 and 2.) The next change usually is a destruction of the epithelial covering upon the summit of the nodule. Softening now begins at the apex and extends downward; the reticulum of the nodule breaking down, the round cells escape as pus into the intestine. (Fig. 2, *F.*) Sometimes softening begins at the centre of the nodule and rupture occurs. The destruction of the whole nodule leaves behind a tiny cavity, which is the follicular ulcer. At first the ulcers correspond in size to the nodule, but the adjacent tissue has meanwhile become infiltrated with a dense accumulation of round cells all about it, and this tissue becomes necrotic. The ulcer extends chiefly in the submucous coat. The overlying mucosa may slough or fall in upon the muscular layer. The ulcers have now quite a wide base and a constricted orifice. (Fig. 3, *F.*) These may extend to form large sloughs by the coalescence of small ulcers, but usually do not. The inflammatory process is never limited to the lymph-nodules; the amount of other change found depends upon the severity and very much upon the duration of the process. In cases dying after a week's or ten days' illness we usually find very little change in the mucosa, and in the submucosa sometimes none and sometimes a moderate infiltration of round cells, especially about the small veins. (Fig. 2, *V, V.*)

In those which have lasted three or four weeks we commonly find all the structures of the intestine in the neighborhood of the ulcers invaded. The mucosa is packed with new round cells, separating the tubular glands or in some cases destroying them; and all about the ulcer in the submucosa are cells in great numbers. They form the floor of the ulcer, and may spread along the lymph-spaces between the bundles of muscle-fibres and even infiltrate the muscular coat. (Fig. 3.) The ulcers stop almost invariably at the circular muscular coat. In only one case have I seen any destruction of this; perforation I have never seen.

The small follicular ulcers may readily be confounded with the simple post-mortem changes in the lymph-nodules. (Compare paragraph on post-mortem changes.)

The nature of the process by which the superficial ulcers (Photo. III.) are formed is not quite so clear. The inflammation starts evidently from lymph-nodules. There seems to be first a sloughing of the mucosa overlying the nodule, and the process extends not deeply into the nodule but laterally in the mucosa; the large ulcers form by a coalescence of the small circular ones, by a continuance of the same necrotic process. The submucosa beneath these ulcers is densely packed with round cells, but never seems to be involved in the destructive process. (See Fig. 4.) These cases

Fig. 1.



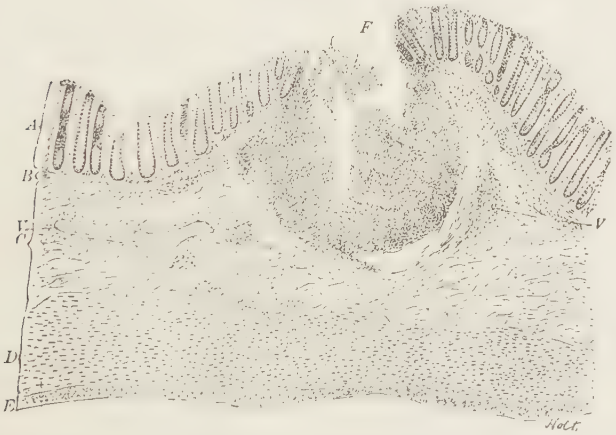
Chronic Hyperplasia of Lymph-Nodules of Colon.

History.—Well-nourished infant, ten months old; died of acute pneumonia without intestinal complications; chronic dyspeptic catarrh from birth till five months old; nursed by mother; stools became normal without treatment, and were so till death.

Autopsy.—Twenty-six hours. Small intestine normal; whole colon showed marked enlargement of lymph-nodules; gross appearances shown in Photos. I. and II.

Three lymph-nodules (solitary follicles), *F*, *F′*, and *F″*, are shown. They are alike in size and situation; the difference in appearance depends on the direction of the section. The nodule at *F* is cut through the centre; the others near their margins. The mucosa *A* has been lifted by the swollen nodules. The summit of the largest nodule, *F*, has been eroded, forming the central pit-like depression seen in many nodules in Photo. II. It is a post-mortem change, but closely resembles commencing ulceration. Other post-mortem changes shown are the loss of superficial epithelium and the falling out of the tubular glands at *T*, *T*, *T*. The submucosa *C* is normal. At *M* is an accidental rent, separating the muscular coats *D* and *E*. *V*, *V*, are veins. The irregularity in the tubular glands seen in the right half of the drawing is due to a slight obliquity in the section.

Fig. 2.

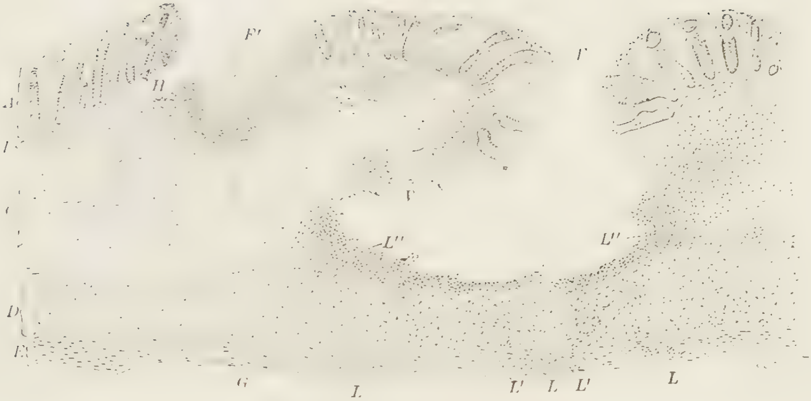


Lymph-Nodule of Colon in the Early Stage of Ulceration (Follicular Ulcer).

History.—Delicate child, thirteen months old; slight diarrhœa four weeks; acute severe symptoms five days; temperature 101° to 103° F.; all stools contained traces of blood; a few clots.

Autopsy.—Intense congestion throughout colon and great numbers of circular ulcers one-twelfth inch in diameter; one of these is shown in the figure. *A*, mucosa; *B*, muscularis mucosæ; *C*, submucosa; *D*, circular; *E*, longitudinal muscular (section is transverse); *F*, follicular ulcer. The nodule is much enlarged, but is softening, breaking down, and discharging itself into the intestine. The overlying mucosa has been destroyed. The superficial epithelium is gone. The tubular glands are essentially normal, but at their bases and just above the muscularis mucosæ is seen a moderate cell-infiltration, which is more marked just beneath the muscularis. There are also nests of new cells about the small blood-vessels *V*, *V*, etc. The vessel to the left of the drawing is cut longitudinally.

FIG. 3.



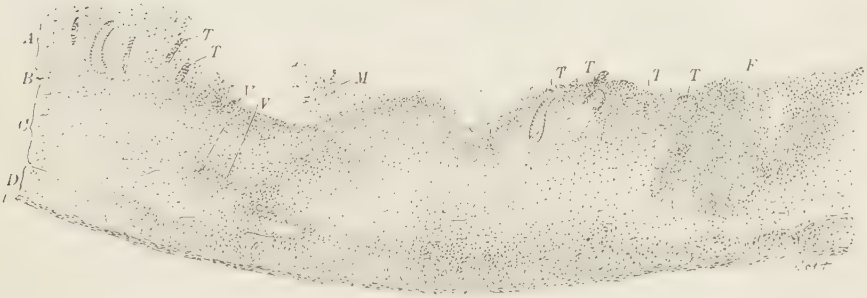
DEEP FOLLICULAR ULCER OF COLON.

History.—Thirteen months old; severe continuous intestinal symptoms three weeks; no blood in stools.

Autopsy.—Thirty-six hours. Numerous ulcers throughout colon; the largest nearly one half inch in diameter in sigmoid flexure. The drawing is of one of the smaller ones, similar to smaller ones shown in Photo. V. *A*, mucosa; *B*, muscularis; *C*, submucosa; *D*, circular; *E*. longitudinal muscular; *F*, deep follicular ulcer; *F′*, superficial ulcer. All trace of lymph-nodule from which the ulcer *F* had its origin has disappeared; the destructive process has extended laterally in the submucosa, and the mucosa is falling in to fill up the space. The base of the ulcer is filled with round cells, *L″*, *L″*. Cell-infiltration has also occurred in the lymph-spaces between the bundles of circular muscle fibres at *L′*, *L′*; nests of cells are also seen in the muscular coat at *L*, *L*. *F′* is a superficial ulcer formed by destruction of the mucosa overlying the nodule. At *H* the mucosa has loosened from the submucosa.

The mucosa is extensively infiltrated with round cells. The tubular glands in some places have been compressed and destroyed; in others they are dilated and filled with new cells. Nests of cells are seen in many places about the small veins *V*. The whole intestinal wall is involved.

FIG. 4.

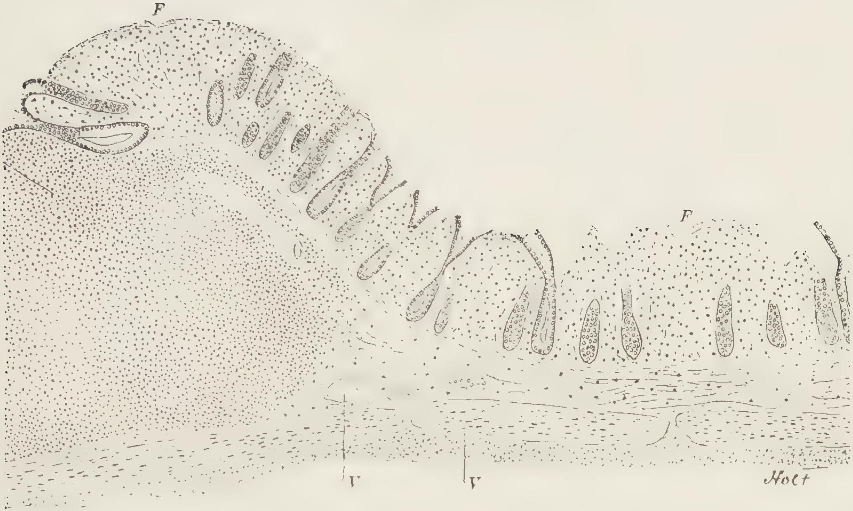


BROAD SUPERFICIAL ULCER OF COLON.

History.—Infant seven months old; continuous severe intestinal symptoms for four weeks.

Autopsy.—Thirty-three hours. Ulcers throughout colon; largest in descending colon and rectum. The gross appearances of similar ulcers are shown in Photo. III., C, and Photo. IV. One edge of a broad shallow ulcer is shown in the drawing. Only at the extreme left, *A*, does the mucosa appear. Here it is infiltrated with round cells and shows only a few remains of tubular glands, *T*, *T*. At *M* a ragged fragment of the mucosa still remains attached. The submucosa, *C*, is densely packed with new cells. They are more numerous in the upper part, which forms the base of the ulcer. Here and there towards the right are seen, at *T*, *T*, *T*, small remains of tubular glands. *F* is a lymph-nodule enlarged and beginning to soften. The muscular coats *D* and *E* are normal. The ulcer involves the mucosa only.

Fig. 5.



Acute Catarrhal Inflammation of Ileum, Mild Form.

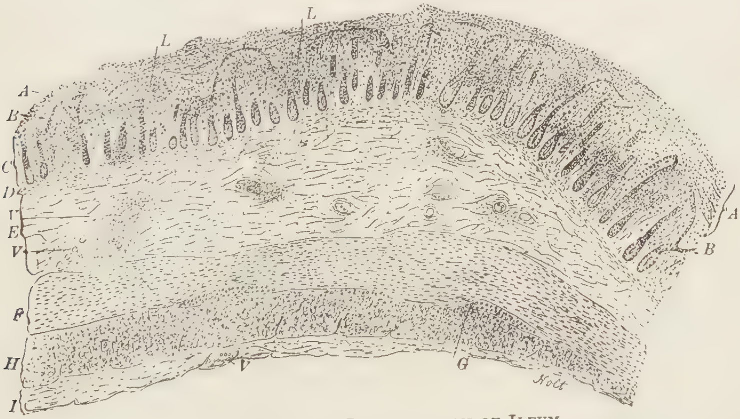
History.—Nine months old; previously healthy; three days sick, with acute intestinal symptoms; temperature 103° to 105° F.

Autopsy.—Two hours. Acute catarrhal inflammation throughout greater part of small intestine and in colon. Peyer's patches acutely congested and swollen. Section shown in drawing is from lower ileum.

In the left of the drawing is seen the edge of a Peyer's patch greatly swollen. Among the other signs of disease shown is almost complete loss of the superficial epithelial layer, this being present in places at the mouths of the tubular glands. Especial attention is called to the epithelial changes, this being a very early autopsy. In several places, as at *F*, *F*, tubular glands have also loosened and fallen out. There is a moderate infiltration with new cells of the entire mucosa, more marked near the Peyer's patch. The submucosa and muscular coats are normal.

(This drawing has been reduced less in the reproduction than the others, except Fig. 8.)

Fig. 6.



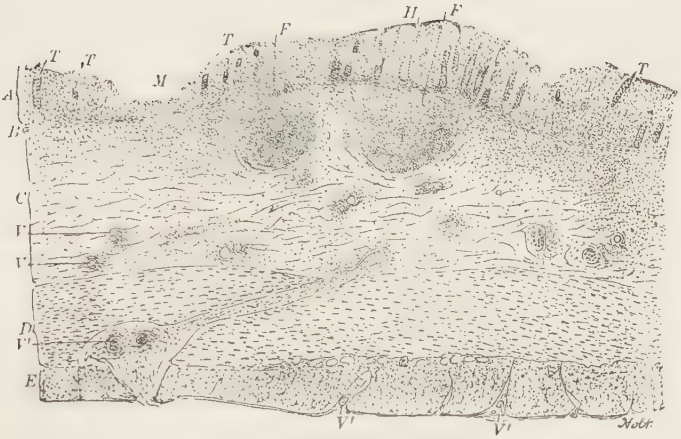
Acute Catarrhal Inflammation of Ileum.

History.—Six months old; mild diarrhœa twelve days, severe symptoms six days, with high temperature.

Autopsy.—Eight hours. Whole colon and lower two feet of ileum involved. Intestine congested, swollen, and much thickened. A grayish exudate on the surface of the lower ileum "resembling pseudo-membrane." The drawing shows a section from this region. *A*, *A*, is the exudation, which is composed of mucus and cells, but no fibrin. *B* is the superficial epithelial layer, the arches of which as it covers the villi are imperfectly preserved beneath the surface-exudation. *C* is the mucosa; the tubular glands are almost all seen. It is thickened chiefly from extensive cell-infiltration, which is seen everywhere, but here and there, as at *L*, *L*, the cells are so numerous as almost to efface the tubular glands and elsewhere to compress them.

The changes are almost exclusively in the mucosa. In the submucosa only a few new cells are seen, chiefly about small blood-vessels, as at *V*, *V*. The muscular coats *F* and *H* are normal. *I* is the subserous connective tissue. *G* is a sympathetic ganglion.

FIG. 7.



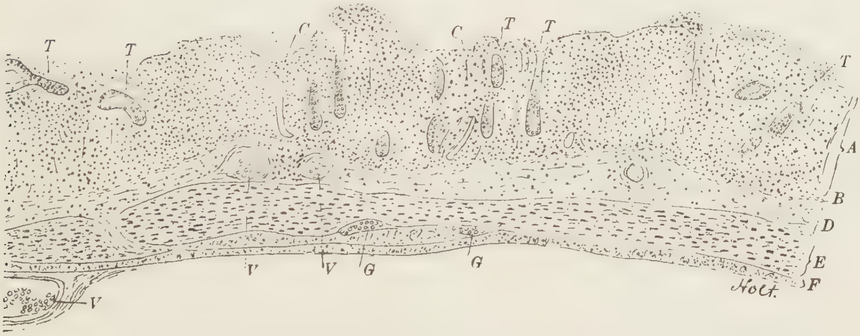
ACUTE CATARRHAL COLITIS, SEVERE FORM.

History.—Ten months old; breast-fed; previously healthy; sudden invasion, severe symptoms; temperature 102° to 106° F.; death in three days.

Autopsy.—Ten hours. Catarrhal inflammation in lower half of small intestine and whole colon, most intense in its lower portion. The drawing is of a specimen from the rectum. The mucosa, *A*, shows a great infiltration of new cells, with destruction of tubular glands; in places only small remains of these, *T, T, T*, are left. At *M* is a superficial erosion or catarrhal ulcer. Another is seen near the right extremity of the drawing. The superficial epithelium is gone, except at *H*, where it is present for a short distance.

The submucosa, *C*, is densely infiltrated with cells, especially at its upper part and about the small blood-vessels *V, V*. *V′, V′*, are blood-vessels piercing the muscular coats. The thickening of the intestine is chiefly due to infiltration of the submucosa. *F, F*, are solitary lymph-nodules moderately swollen.

FIG. 8



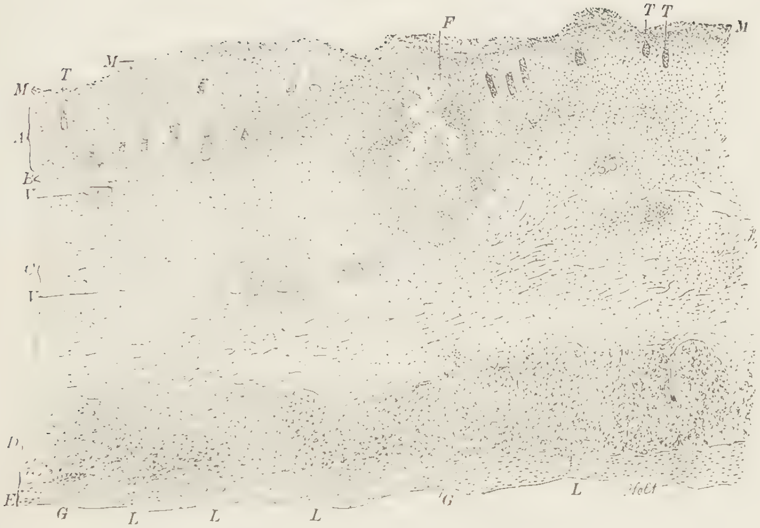
CHRONIC CATARRHAL INFLAMMATION OF THE ILEUM.

History.—Delicate child, thirteen months old; continuous intestinal symptoms for four months; during first two weeks high temperature; progressive wasting; weight just before death, eight pounds.

Autopsy.—Thirty hours. Gross changes slight; the section is from the middle ileum. A similar condition existed through a considerable part of the small intestine irregularly distributed, and also in the stomach. Slight changes in the colon. The lesions affect the mucosa, *A*, almost exclusively. It is much thickened, being considerably thicker than the other coats combined (compare Fig. 6). The tubular glands are extensively destroyed, some remains being seen at *T, T, T*, etc.; the villi scarcely project at all. There is a very great increase in cells, and some new connective tissue in the mucosa. Large capillary vessels are seen at *C, C*. The submucosa is thinner than normal, and contains many large blood-vessels, *V, V*. About some of them a small increase of cells is seen. *G, G*, are sympathetic ganglia. The muscular coats *E, F*, are a little thinner than normal.

(This drawing has been reduced less in the reproduction than the others, except Fig. 5.)

FIG. 9.



CROUPOUS INFLAMMATION OF THE COLON.

History.—Fourteen months old; ill nine days; temperature 101° to 105° F.; all stools containing blood, some small clots.

Autopsy.—Thirty-six hours. Lesions in lower ileum and whole colon; great thickening of intestine and pseudo-membrane in places; most marked changes in ascending colon, from which the specimen shown in the drawing is taken. *M*, *M*, is the pseudo-membrane, composed chiefly of granular fibrin. The mucosa, *A*, shows dense infiltration of cells, so great that tubular glands are almost entirely destroyed, small remains only being seen at *T*, *T*. In the right of the drawing the muscularis mucosa is also obliterated. It is seen in the left at *B*. The submucosa, *C*, is greatly thickened; this is partly due to the great accumulation of round cells seen quite to the muscular coat, but chiefly to fibrin, which the high power shows to infiltrate this coat everywhere, and also the mucosa. There are accumulations of cells at *L*, *L*, in the muscular coats. *V*, *V*, are small vessels with zones of cell-infiltration about them. *F* is a solitary lymph-nodule covered by the pseudo-membrane, but breaking down in its centre. *G*, *G*, are sympathetic ganglia.

do not appear to me to be croupous, for the reason that I have never been able to find any fibrin in the exudation elsewhere, and nothing comparable in any way to them has been seen in any of the croupous cases examined.

The mode of healing of the follicular ulcers will be considered among the lesions of chronic inflammation of the intestine. This termination is, unfortunately, a rare one. I have seen only three cases in which healing or healed ulcers were found in the intestines in children. Ulcerative inflammation then is almost always fatal.

IV. **Acute Croupous Inflammation.**—This is the most severe form of intestinal inflammation seen in children. The terms "croupous" and "diphtheritic" are hardly descriptive, for the process differs quite materially from what is described as occurring among adults.

Frequency.—This lesion was found in nine out of seventy fatal cases. It is usually primary, being a very rare complication of diphtheria of the pharynx. The only instance I have seen was a specimen presented by Dr. Sellew[22] to the New York Pathological Society.

Clinically, this form usually runs a short, intense course, with a continuous temperature which is moderately high, severe general symptoms, and death generally in eight or ten days. The shortest case I have seen lasted six days. If recovery takes place, it is only after a very prolonged illness.

Gross Appearances.—There is visible to the naked eye very little pseudomembrane and no deep sloughing. The lesion affects with remarkable uniformity the last two or three feet of the ileum and the whole colon. It is exceedingly rare to meet with any marked lesions high up in the small intestine. The most marked changes are usually in the neighborhood of the ileo-cæcal valve. They are quite as severe in the ileum as in the colon, but the process stops very abruptly. (See Photo. VII.) Often within a few inches we have a transition from a part the seat of intense inflammation to a nearly normal intestine. Next to the cæcal region the most severe lesions are usually found in the sigmoid flexure and the rectum.

The intestinal contents are usually green or greenish-brown mucus and fæcal masses mixed with remains of food; occasionally they are of a brown coffee-ground color, almost never bloody. There is but little gas in the colon, and often it is nearly empty throughout.

The intestinal wall is firm and stiff, and is from two to four times the normal thickness. It is not thrown into deep folds, as is healthy intestine when empty. It is very rare to find false membrane that can be stripped off in patches of any considerable size. Where membrane exists, the color is a grayish green, and the surface is often fissured, giving a lobulated appearance. In the parts where no pseudo-membrane can be seen, the surface is usually of an intense red color, and is rough and granular, in striking contrast to the normal glistening appearance. (See Photo. VII.) Here and there small extravasations of blood can be seen in the mucous membrane, the largest of which may be half an inch long. Peyer's patches and the solitary lymph-nodules of the intestine are indistinct, and often cannot be made out at all: nor can the villi be seen in the ileum. There are rarely any ulcers visible to the naked eye, unless this process is complicated by follicular ulceration, which is uncommon.

Although the whole colon is involved, the lesions differ very much in degree in the different regions, and it is very rare to find pseudo-membrane covering any considerable area. It is often limited to a few inches. In a single instance I have found a coating of fibrin on the peritoneal surface for a short distance. The small intestine above the lower ileum shows no constant or peculiar changes. It may present the changes of a slight catarrhal inflammation, but is quite as often essentially normal. In a very small proportion of the cases coexisting inflammation of the stomach is present.

Microscopical Appearances.—Under the microscope the changes are strikingly uniform. There is a dense infiltration of the mucosa with round cells, and usually of the submucosa also; there is wide-spread and often entire destruction of the tubular glands; fibrin coats the surface in a few places, in many there is none, in a very few cases there is some infiltration of fibrin into the deeper tissues. The lymph-nodules do not participate actively in the process.

The cell-infiltration is a marked feature, and occurs in irregular areas. In some places it is so dense as to efface all the normal elements of the mucous membrane. When not so abundant, the cells are more numerous in the upper part of the mucosa than in the lower: they compress the tubular glands, often causing them to assume a flask-like contour. In the submucosa the cells are especially abundant in two situations,—just beneath the muscularis mucosæ, and about the small veins. Exceptionally the whole submucosa is densely packed quite to the muscular coat. Nests of cells may even be seen in the muscular layer or in the subserous cellular tissue. These cells are small round lymphoid cells. (See Fig. 9.)

The tubular glands in places are entirely destroyed, not a vestige remaining for some little distance. In other places we see, here and there, small remains of these structures,—usually the deeper parts, those more superficial having disappeared. In still other places we see them widely separated by the accumulation of cells, and variously compressed and distorted.

Where the tubular glands have disappeared entirely, the mucosa is filled with granular detritus of broken-down cells, round cells which infiltrate the adenoid tissue between the glands, and sometimes fibrin.

Fibrin is seen in most cases upon the surface only, and here only in certain parts of the specimen. The amount is usually small; in some we can scarcely find any. Fibrin is often found under the microscope in the "granular" parts of the specimen, where no pseudo-membrane could be made out by the naked eye. In a few cases coagulated fibrin is seen in the adenoid tissue of the mucosa, in the interstices of the connective tissue of the submucosa, and even upon the peritoneal surface. The pseudo-membrane upon the surface usually amounts to about one-fourth the thickness of the normal mucosa. It is made either of granular fibrin containing but few cells, or a net-work filled with round cells and often red blood-globules. Bacteria are present, but not usually numerous.

It is to the dense cell-infiltration of the submucosa, and the coagulated fibrin here, with usually some œdema, that the chief increase in thickness of the intestine is due, rather than to the pseudo-membrane on the surface.

The muscular coats show no changes beyond round-celled infiltration and, more rarely, coagulated fibrin.

The blood-vessels are everywhere gorged with blood. Sometimes the submucosa seems literally filled with these distended vessels. Even the small vessels of the mucosa are greatly increased in size. In many cases we find smaller or larger extravasations of red blood-globules into the mucosa or the submucosa.

Sloughing, with the formation of deep ulcers, I have never seen in this process in children. In this respect there is a striking contrast with the adult cases.

There is but little change of the lymph-nodules unless they have been diseased preceding the croupous inflammation. In these instances we may have great swelling of the nodules, and even the formation of follicular ulcers; but this combination is rare.

OTHER LESIONS PRESENT IN CASES OF ACUTE DIARRHŒAL DISEASES.—*Brain.*—Notwithstanding the frequency of cerebral symptoms, it is very exceptional to find any sufficient explanation for them in the appearances seen at the autopsy. Overlapping of the bones of the skull to a slight degree is occasionally seen in the rapidly-fatal cases in very young infants. A slight increase of the cerebro-spinal fluid is not uncommon, but seems to me of no special significance. Thrombosis of the sinuses of the dura I have never seen, although others have described it. It is certainly not a frequent lesion. Congestion of the brain is not infrequently seen in cases dying with high temperature and convulsions, but apart from the latter symptom it has not seemed to be more common or more striking than in the generality of autopsies. In a single case I have seen a very marked anæmia of the brain which seemed to be the explanation of the cerebral symptoms. They were so decided in this patient that the case was regarded as one of undoubted meningitis. The brain was almost bloodless.

Mouth.—The catarrhal and follicular forms of stomatitis are quite frequent. They are discussed under symptomatology.

Lungs.—Tuberculosis has been met with in several cases where the patients died of intestinal disease in no way connected with tuberculosis. By far the most frequent lesion in the lungs was broncho-pneumonia. It was present in one-sixth of all the cases. In the cases which had lasted ten days or over it was present in nearly one-half. In six cases it was the immediate cause of death. In the others the amount of pneumonia was small. The most common variety is a subacute form which develops in the dependent portions of both lungs, being usually most marked in the lower lobes. Less frequently the acute form was seen resulting in more or less diffuse areas of consolidation in one or more lobes.

In a single instance complicating ulcerative colitis I have met with a case of pneumonia in which a large abscess formed in the upper lobe of the lung. There were no other abscesses in the body, and no tuberculosis. There is nothing peculiar in the pneumonia complicating intestinal disease. It occurs just about as frequently and with precisely similar appearances in other diseases whose general symptoms and course are similar. More or less congestion of the lungs, usually hypostatic, is seen in nearly every case.

Pleurisy I have never seen apart from pneumonia or tuberculosis. Bronchitis of the larger tubes is very common.

Heart.—This organ is usually pale and contracted. I have never met with any lesion of importance in the endocardium, pericardium, or heart-muscle.

Intussusceptions were seen in about ten per cent. of the cases; they were most frequently met with in the short, acute cases. They are multiple, very often twelve or fifteen in one case. They are undoubtedly produced during the death-agony, and are of no pathological importance.

Peritoneum.—General peritonitis was never seen, nor was serous transudation into the peritoneal cavity. Localized plastic peritonitis was met with in a single case of croupous inflammation.

Kidneys.—Ever since the writings of Kjellberg[23] it has been the custom to speak of the great frequency of nephritis in these cases. My own observations have not confirmed his results. I have found well-marked nephritis in but a single case. Cloudy swelling of the epithelium of the tubules is very common, and is seen in almost all cases where the temperature has been high. Taking the cases as a group, however, the renal changes are just what one meets with in pneumonia or in any other acute febrile disease, but are no more marked.

Liver.—In the acute cases there have been no constant or characteristic changes. The organ is frequently pale, but in all other respects normal.

Spleen.—In a small number of cases I have found the spleen moderately swollen, but in the majority there is nothing abnormal either in its size or in its general appearance.

Stomach.—As microscopical examinations of this organ have not been made in all cases, it is impossible to state the exact frequency with which the stomach was involved. In the acute desquamative cases, changes in the stomach were quite constant and closely resembled those seen in the intestines. In two or three instances they were more pronounced than in the intestines.

In the acute catarrhal cases the stomach was involved in about one-half the cases. In the acute croupous cases and in the cases of follicular ulceration it was quite exceptional to find lesions in the stomach.

Mesenteric Glands.—These lymph-nodes are involved in almost every case. In the most recent ones they are red, in those of longer duration sometimes pale. In no instance were they softened or broken down.

The lesions of the skin are considered among the symptoms.

V. Chronic Inflammations of the Intestine.—I have included under this head several varieties differing quite widely.

1. Chronic Hyperplasia of the Lymph-Nodules.—This may occur as a primary or as a secondary condition. It is found in infants who have suffered for weeks or months from the symptoms known as chronic dyspeptic catarrh, occurring more often in those who are cachectic. It is also seen in those who have previously suffered from repeated mild attacks of diarrhœa, and sometimes when there is a history of antecedent severe diarrhœa. The lesion is apparently not of so much importance *per se* as in its relation to acute inflammation and ulceration of the lymph-nodules. A study of the clinical history of these cases seems to show that the existence of these swollen lymph-nodules predisposes strongly to follicular ulceration.

The gross appearances of these enlarged lymph-nodules have already been described under acute catarrhal inflammation. In those occurring slowly they are usually more of a yellowish color. They are found almost exclusively in the colon, those of the small intestine and Peyer's patches participating but rarely. (See Photos. I. and II.)

Pigmentation occurs in a few of these cases, but in most it is absent. There may be some slight congestion of the mucous membrane, but nothing of any moment.

Microscopically, there is seen chiefly an enormous increase in the number of cells of which these nodules are largely made up. The swollen nodules raise the mucosa and crowd the tubular glands aside, infiltrating the tissues immediately overlying them. (See Fig. 1.) Otherwise there are no intestinal changes belonging to this condition. Once produced, these hyperplastic nodules are very slow in disappearing: they may last indefinitely. I have found them in one case five months after the cessation of all symptoms.

The lymph-nodes lying in the mesentery (mesenteric glands) are invariably found to be swollen, and frequently reach the size of an inch in length and half an inch in thickness. They are generally of a pale-gray color. Microscopically they give the usual appearance of swollen lymph-nodules elsewhere in the body. They show no tendency to caseation or abscess.

2. Chronic Catarrhal Inflammation following the Acute Form.—This lesion is not nearly so frequent as might be supposed from clinical observation. In a great number of the cases where acute attacks have been followed by more or less persistent intestinal symptoms, we find little else than the hyperplasia of the lymph-nodules just described. As in the acute catarrhal variety, this lesion is more likely to involve the small intestine than are some of the other pathological processes. It is likely to be wide-spread, although differing very much in intensity in different regions.

Gross Appearances.—These are not characteristic, and differ so little from those of normal intestine that they may be easily overlooked. Closer examination of the small intestine may show to the naked eye, but it is better seen with a lens, that the villi are much less distinct than normal, and in places are wanting altogether. The intestine may be distended until it is as thin as parchment, or it may be thicker and firmer than normal. There is no recent congestion, the usual color being slate-color or gray. Sometimes dark streaks of pigmentation are seen in the general mucous membrane; at other times this is limited to the Peyer's patches and the solitary lymph-nodules.

Peyer's patches are not often enlarged, and they may even be less prominent than normal. The solitary lymph-nodules in the colon usually show more or less enlargement, but no ulceration. The mesenteric lymph-nodes are always enlarged, but usually pale.

Microscopical Appearances.—These are striking, and are often a great surprise when so little change has been seen in the gross specimen. The lesion is essentially one of the mucosa; the essential features are a disappearance of very many of the tubular glands, and, in the small intestine, of the villi also; a very great proliferation of cells in the adenoid tissue of the mucosa, and, if the disease has existed long enough, a production of new connective tissue. (Fig. 8.)

The lesions are found irregularly distributed; in places there may be complete obliteration of the normal elements of the mucosa, while in others they are very little altered. The superficial epithelium is often entirely gone for a considerable extent. If the reparative process has begun, in certain parts it may have been perfectly reproduced.

The tubular glands are small, often completely destroyed; in other places there are seen here and there remains of these structures displaced, compressed, and variously distorted by the inflammatory products. In the regions most affected the villi have ceased to project much above the rest of the mucosa, and have the appearance of being matted into the mass of inflammatory materials, so that all trace of their original contour is lost. But a little distance from these areas we may find others in which the changes are slight.

There is a very marked infiltration of the mucosa with round cells, but the submucosa is usually free from them. The mucosa is made up of these cells, the remains of villi and tubular glands, dilated blood-vessels, the normal reticulum of the adenoid tissue, and, if the lesions are old, new connective tissue has formed. As Woodward[20] has observed, it takes a very long time for connective tissue to form in these cases, contrasting in a striking way with the rapidity with which it develops in the healing of ulcers.

The submucosa is usually thinner than normal, but may be thickened from cell-infiltration and the production of new connective tissue. Atrophy of the muscular coats has been described by some writers, but I have not seen any that was pronounced. The blood-vessels are found very much enlarged. Amyloid degeneration of their walls I have not seen.

The solitary lymph-nodules of the colon may show nothing more than the changes described in the previous paragraph, or there may be a slight increase in fibrous trabeculæ; but I have met with no changes marked enough to deserve the term of induration or sclerosis, as described by Baginsky,[4] or as seen among adults by Nothnagel.[21]

These cases differ very much in the extent and distribution of the lesions; the longer they have lasted the more widely spread they are. The only typical example I have had an opportunity to study showed very marked changes in the small intestine, similar but less pronounced in the stomach, and very slight in the colon.

3. CHRONIC INFLAMMATION FOLLOWING THE ACUTE CROUPOUS FORM is described as occurring in adults where ulcers have formed from the process of sloughing. Sloughing is a very rare occurrence in infancy, and an acute inflammation of such severity would be almost certainly fatal. I have never seen such ulcers, nor have I met with a clear description of them.

4. CHRONIC INFLAMMATION FOLLOWING FOLLICULAR ULCERATION.—This is but infrequently seen at autopsy, since nearly all the cases of ulceration terminate fatally in the acute stage. They sometimes linger along for several months with continuous intestinal symptoms, and die of some intercurrent disease, most frequently of pneumonia. At autopsy we find these ulcers in various stages of repair, and sometimes associated with the formation of cysts.

(1) *The Mode of Healing of Follicular Ulcers.*—The overhanging edges described in the acute cases (see Fig. 3) fall in upon the submucous or muscular coat, as the case may be. The pit-like cavity left is partly filled up by granulation-tissue; new connective tissue develops in the mucosa between the tubular glands and in the submucosa. New epithelium forms very readily over the granulation-tissue which fills the cavity, and there may be left a simple indentation scarcely noticeable, or a broader cup-shaped depression; or, if the ulcers have been larger, the cicatricial tissue which forms is so abundant that its contraction may cause a puckering in the surface, sometimes a stellate cicatrix.

The time required for the process of healing varies, no doubt, much in the different cases and in different parts of the intestine, so that we may find at the same time ulcers entirely healed and those in which the process of repair is scarcely begun. From two to three months seem to be required in the case of ulcers of the average size.

It is extremely doubtful if stricture ever results from this form of ulceration in children.

The rest of the intestine in these cases shows the lesions of a more or less severe chronic catarrhal inflammation.

(2) *The Formation of Cysts in the Colon.*—This is one of the rarest lesions seen in chronic inflammation of the intestine. I have placed this lesion among the changes associated with follicular ulceration, although some hold it to belong rather to the catarrhal cases. The fully-developed cysts

I have seen in but a single case. There was in this case first an ordinary attack of acute entero-colitis in a child a year and a half old, which gradually passed into a chronic condition, the intestinal symptoms lasting four or five months continuously. The infant never regained his health, and died about a year later from intercurrent disease.

In the descending colon and rectum about twenty of the larger cysts were found, and some smaller ones. The larger cysts were about one-sixth of an inch in diameter, and had a very thin, transparent membrane covering them, through which their colorless contents were distinctly visible. They projected considerably from the intestine, but were sessile. Upon section their mucoid contents escaped. It was perfectly transparent, and in general appearance and consistency resembled the vitreous humor of the eye. The smaller cysts appeared only as small warty elevations in the mucous membrane, which had its normal color. The only other essential lesions in the intestines were cicatrized follicular ulcers. The microscopical examination in this case gave no clue to the origin of these cysts. They were found to be situated in the submucosa, covered by a mucosa more or less attenuated, in some places differing but slightly from the mucosa a little distant. The capsule showed no trace of epithelial lining.

These cysts have been fully described by Woodward, who has given the only account of them I have seen in English. He states that they were first fully described by Kelsch[24] in 1873.

They are undoubtedly produced by dilatation of the tubular glands, some of which sink or grow into the submucosa in the space occupied by softened or ulcerated lymph-nodules. The orifice becomes closed, and the tubule becomes distended by the accumulated pent-up secretion of the mucus-cells of the gland. I have myself seen, in one autopsy, upon a case of follicular ulceration of eight weeks' standing, the early stage of this process.

Amyloid Degeneration is rarely seen in infancy. It is not so rare in older children, where it occurs with amyloid degeneration of the liver, spleen, and kidneys, most frequently as a result of prolonged suppuration with chronic bone- or joint-diseases. It may occur in syphilis or tuberculosis.

The symptomatology of these cases is still unsettled. The process begins by affecting the walls of the arterioles and capillaries, particularly of the villi (Woodward), and later the vessels in the submucosa. After the blood-vessels the epithelium may become affected.

The mucous membrane in these cases is pale and rather transperent. Upon the application of the iodine test to the small intestine many red or brown points appear where the villi have been affected.

The Intestines in Athrepsia or Infantile Atrophy.—It seems proper to introduce here a few remarks upon this subject, since certain German and French writers have taken the ground that the essential lesion in a considerable number of these cases is intestinal atrophy,—*i.e.*, a condition similar to what has been described above under the head of chronic catarrhal inflammation.

I have examined microscopically the intestines of twenty cases of athrepsia or marasmus. Fourteen of these cases died with intestinal symptoms, usually of short duration. In all of them the symptoms of marasmus had existed long before the intestinal disorder. In the remaining six there were no special intestinal symptoms.

In no case of either series was there anything bearing the least resemblance to "intestinal atrophy." The diarrhœal cases usually showed only the changes described as acute desquamative catarrh of a mild degree, the lesions being, as a rule, less pronounced than those seen in children who were previously in fair condition, probably because the former class succumb readily to disease of no great severity.

In the six cases without intestinal symptoms there was practically nothing abnormal in the intestines. Two cases in which autopsies were made three and four hours respectively after death, showed intestines as nearly normal as I have ever met with in an infant. In view of these facts, we cannot accept without further evidence the proposition that the cases of primary infantile marasmus or athrepsia are to be explained by intestinal atrophy.

OTHER LESIONS IN CHRONIC INFLAMMATIONS.—Those belonging to the skin, mouth, and eyes are considered in the section upon symptomatology.

The lesions of the brain are for the most part accidental complications. Hydrocephalus and chronic meningitis have been met with occasionally, but they are rare.

The pulmonary lesions are essentially those already described in the acute forms of inflammation of the intestines. They consist of hypostatic congestion, subacute or chronic broncho-pneumonia, and pulmonary tuberculosis.

The liver has been found extremely fatty in one or two cases, but hepatic abscess as a result of intestinal ulceration has never been met with.

The kidneys nearly always show more or less of cloudy swelling, and in one case I have seen a pronounced degree of chronic nephritis.

Dropsical effusions into the serous cavities are not frequent, but are sometimes met with.

General tuberculosis is a very frequent cause of death.

IV. THE STOOLS IN DIARRHŒAL DISEASES.

A healthy stool of a nursing infant or one upon an exclusive milk diet varies in color from a pale yellow to a deep orange; it is smooth, homogeneous, and of a butter-like consistency, acid in reaction, of a slightly sour but not disagreeable odor. The reaction depends upon the presence of lactic acid (Uffelmann[25]), the source of which is the milk-sugar. The color is due to bilirubin.

The only gases present are H and CO_2 (Escherich); H_2S and CH_4, to which the odor of adult stools is largely due, are not present. The following chemical analysis is from Wegscheider:[26]

Water, average		85.13
Solids	organic, 13.71 inorganic, 1.16	14.87
		100.

There are no peculiar albuminoids; those existing in mother's milk seem to have been almost completely absorbed.* Peptone exists only in very small amount. Sugar is absent.

Fat is the chief organic ingredient: it is found as unaltered fat, free fatty acids, and saponified. Of biliary elements, there are hydro-bilirubin, unchanged bilirubin, and cholesterin in considerable amount. The presence of biliary acids is doubtful.

Of ferments, pepsin is absent, but there are traces of the pancreatic ferments.

Mucus is always present in considerable amount; also columnar intestinal epithelium. Leucin, tyrosin, and other products of albuminous decomposition, phenol and scatol, are absent; indol is rarely found. (Uffelmann). The inorganic salts are chiefly those of lime.

Microscopically, there are seen epithelial cells, chiefly columnar, a few round cells, mucus-corpuscles, fat-globules and crystals of fatty acids, cholesterin, mucin, protein substance, crystalline inorganic salts, sometimes bilirubin in crystals, yeast fungi, and bacteria in immense numbers, chiefly the bacterium coli commune of Escherich.

The number of stools during the first two weeks is from three to six daily. After the first month two stools a day are the average; many infants have three, many others but one.

As soon as an infant is put upon a mixed diet the peculiar characters of the stools cease, and they come to resemble more those of the adult, though remaining softer and thinner throughout infancy. They become darker in color, and assume the adult odor, while retaining their acid reaction. The bacteria, while still in great numbers, are no longer of the single variety met with almost exclusively in milk stools.

STOOLS IN DISEASE.

As a rule, in all varieties of intestinal catarrh the number of stools is increased. An exception is in certain forms of chronic catarrh, like that occurring in rickets, where the number may be less than in health, or where diarrhœa may alternate with constipation, the same pathological process existing in both cases.

---

* Tschernoff (*Jahrb. für Kinderheilk.*, Bd. xxviii. H. 1) publishes analyses of the albuminous matter of stools, estimated from the amount of nitrogen, which differ very materially from those previously made by Wegscheider, Uffelmann, and others. He makes the amount of albuminous matter many times greater.

In diarrhœa the number of stools may reach twenty a day, or even more. Usually the number is inversely proportional to the size of the stools,—an exception being the case in choleraic diarrhœa, where the discharges, although large, may be repeated every half-hour.

Consistency.—This depends upon the amount of water, mucus, and fat present. It is rarely the case that stools in disease are thicker than normal, but it sometimes happens that loose stools alternate with stools of an ashy-gray color, thick, dry, and of a very foul odor. These stools contain large amounts of fat. The amount of water and mucus usually predominates so much over the increase in fat that diarrhœal stools are much thinner than normal. They may be almost pure water, so that the napkins are soaked without any solid deposit upon them. These watery stools are never seen at the beginning of an attack, but may supervene in the course of an illness at any time; they are always an unfavorable symptom, and a return to more consistent stools is a sign of improvement.

Reaction.—The great proportion of stools in diarrhœal disease, as in health, are acid; the next most frequent condition is a neutral reaction; while distinctly alkaline stools are comparatively uncommon. Thin grass-green stools are usually acid, although this acidity may be less than in health. Alkaline stools are most frequently those which are large, thin, yellow, and very foul, or the choleraic stools, odorless, and almost entirely serous.

It is still a disputed point whether the reaction of the stools is a trustworthy guide to the nature of the process of decomposition going on in the alimentary canal. My own view is that it is of very doubtful value. It varies in the same case from day to day, and is modified to a large degree by food, and somewhat by drugs.

Color.—*Green Stools.*—These are seen in the early stage of almost every case of dyspeptic diarrhœa, and form a striking feature. The color varies all the way from a pale greenish yellow to a bright grass-green. In consistency the stools may be thick or watery; they may be, but are not commonly, of foul odor. They are usually acid, frequently neutral, but rarely alkaline, in my experience. This color may persist through the attack. We cannot accept as conclusive the observations of the French writers Hayem and Lesage,[9] who assert that a specific germ is the cause of the color of these stools. Wegscheider[26] has shown that the green color depends upon preformed biliverdin. The condition in the intestine upon which the transformation of bilirubin into biliverdin depends has been generally regarded as one of acid fermentation. Pfeiffer's[27] experiments seem to show that this long-received opinion is erroneous. In the first place, he found that none of the acids formed in such fermentation,—lactic, acetic, butyric, propionic, etc.,—added to yellow stools outside the body, would turn them green, but made them a deeper yellow. However, dilute alkaline solutions added to fresh yellow stools turned them green after an exposure of thirty to sixty minutes, and strong solutions turned them first brown, and later, after exposure to the air, an intense green.

It is well established that the intestinal tract in a nursing infant is acid throughout. Pfeiffer holds that green stools are evidence of alkalinity somewhere in the canal, any such alkalinity being pathological. The acidity of green stools is not the cause of their color, but depends upon the acid reaction of the colon. It is less, Pfeiffer states, than in normal yellow stools.

Stools which are pale yellow when discharged and which afterwards become green are often seen in disease; they may be themselves neutral or alkaline in reaction, or this may depend on the admixture of urine. Pfeiffer produced typical green stools in a healthy infant by giving two grains of sodium bicarbonate hourly for two days. When this was withheld and hydrochloric acid given, the normal yellow color was restored.

This seems to be the best explanation yet offered for the color of green stools. I have repeated some of Pfeiffer's experiments upon stools, with a confirmation of his results.

In certain cases the stools are green from an excess of bile.

Brown stools may be due to changed biliary pigment, to certain drugs, —bismuth, vegetable astringents containing tannin, or iron. In some instances the color may be almost black. Blood, from the stomach or the small intestine, may give the stools a black, tarry color. The stools of an infant may be brown from a diet consisting largely of broth or other animal foods.

These stools may be of any consistency or reaction. In severe forms of dyspeptic diarrhœa, and sometimes in entero-colitis, we have brown stools which contain almost no solid matter, and are like muddy water, often very offensive in odor.

White or light-gray stools are usually of a putty-like consistency, sometimes like dry balls upon the napkin, sometimes resembling ashes. They are usually exceedingly offensive, and are made up very largely of fat, bile being greatly diminished or absent altogether.

Bright-red stools are due to admixture with blood. If it comes from the lower colon or the rectum, it is not mixed with the stool. If from higher up, it streaks the stool only, or may appear only as brownish-black masses.

Mucus.—Although this is present in all healthy stools, it is so intimately mixed and in such small quantity that it does not appear as mucus to the naked eye. Any such appearance may be regarded as abnormal. Mucus is present in considerable quantity at some stage in the process in almost every case of intestinal disease. It is much more abundant in inflammations of the large than in those of the small intestine, and is especially so in the subacute and chronic forms of colitis.

When from the rectum or the lower colon, it appears in jelly-like masses or shreds, and may make up a large part of the stool. If from the upper colon, it is usually more or less intimately mingled with the rest of the stool; if from the small intestine, this is always so, and, in addition, it is usually bile-stained. Shreds of mucus in the stools may sometimes resemble false membrane. Washing with a stream of water quickly shows the difference; the mucus is broken down, while the other is not affected.

Food-Remains.—*Fat.*—One of the first changes noticed in the composition of dyspeptic stools is the increase of fat. Often the stool as a whole is quite green, but contains small masses of a yellowish-white color which vary in size from a pin's head to a large pea, or even larger. These masses were long regarded as lumps of undigested casein, and were first shown by Wegscheider to consist almost entirely of fat. Baginsky points out that they always contain large colonies of bacteria. These masses may be so numerous that the stool is in great part made up of them. They are distinguished from casein lumps by their solubility in alcohol and in ether.

The term *fat diarrhœa* has been used by Demme[28] to designate this condition in an aggravated form. Since then others have written upon it, especially Biedert.[29] In some of the reported cases the percentage of fat rose from thirteen and nine-tenths per cent., the normal (Uffelmann), to fifty per cent. and even to sixty-four per cent. Of twenty cases observed by Demme, nine were fatal. These cases are to be regarded as extreme cases of intestinal dyspepsia, but whether the liver or the pancreas is at fault we do not as yet know.

Casein is not nearly so common an ingredient of stools as is generally supposed. As stated above, what was formerly regarded as casein has been shown to be almost entirely masses of fat. Genuine casein lumps are usually hard, smooth, and of a yellowish-white color outside, but white within; they give a cheesy odor when broken down. Casein is seen occasionally in semi-transparent, horny masses, of irregular shape, giving the appearance of having been long in the intestine. Casein lumps may be seen at any time in the course of a diarrhœal attack when milk has been given as a food. They bear no relation to the other elements of the stool. In the chronic cases they are most numerous.

Starchy Foods.—In children fed largely upon these substances they appear in the stool in considerable quantity, and may make up a large part of the solid matters of the stool. Certain substances, such as the remains of oatmeal, barley, or wheat, may be evident to the naked eye. Under other circumstances a chemical or microscopical examination of the stool is necessary to discover them. If the amount of starch is large, the addition of the iodine solution may cause the whole stool to change to a dark blue or a black. The microscope shows starch granules more or less broken down and irregularly stained.

Other elements, such as muscle-fibre, etc., are found in more or less quantity, recognized only by the microscope: they are of no special significance.

Epithelial cells are found in large numbers in all diarrhœal stools, and are more abundant in proportion to the acuteness of the process. The great proportion of the cells are cylindrical epithelium. In addition to isolated epithelial cells, numbers are often found attached to a basement-membrane, and even entire tubular glands are sometimes seen, they having loosened and fallen out. The cells are found in all stages of degeneration. To draw any inferences from the state of these cells respecting the condition of the epithelial lining of the intestine seems to me hardly justifiable. Pavement epithelium is rare, and probably comes most frequently from the anus.

Round cells are found, both large and small, in almost all diarrhœal stools. In simple catarrhs their number is not large. Nothnagel has pointed out the striking contrast offered by the intestinal mucous membrane in this respect to that of the respiratory tract. They are found, according to this writer, in large numbers, almost exclusively in the ulcerative forms of inflammation. Baginsky, however, has found round cells in large numbers also in the severe forms of catarrhal inflammation; but they are not so constant a feature. The continued presence of large numbers of round cells in the stools is considered by both these writers to be almost conclusive proof of the existence of intestinal ulceration.

Blood may be in such small quantity as to be recognized only by the microscope, or in large masses, clots, or clear fluid blood. The last two are almost never seen except in inflammation involving the lower portion of the colon and the rectum. Blood from higher up appears in dark tarry masses, or intimately mixed with the rest of the stool.

The source of the blood is almost always the capillary vessels of the mucous membrane; it is very rarely from the opening of larger vessels by ulceration. It belongs, therefore, more commonly to the early stage of congestion, and not to the later one of ulceration. (See symptoms of ulceration.)

Patches or shreds of **pseudo-membrane** are rarely seen in the stools in infancy; they are not quite so rare in later childhood. Stools must be washed with water before such patches are distinguishable.

Parasites.—In the literature of diarrhœal diseases of one or two decades ago, a prominent place was by many writers given to the description of monads and various other infusoria which were found in diarrhœal stools. They were carefully studied first by Lambl,[30] and since him by several writers, including Woodward and Nothnagel, and more recently by Von Jaksch.[31] Their relation to diarrhœal diseases has never been established, and it scarcely seems necessary to describe here the forms studied. They can be found in the writings referred to.

The various forms of intestinal worms are occasionally found in diarrhœal stools, but their presence is accidental only.

Bacteria.—These are found in immense numbers in all stools, healthy and diarrhœal. Morphological descriptions alone of the various forms met with are not only unnecessary but profitless. It is only by cultures that the identity of bacteria can be established. For an account of what has been done with cultures, the reader is referred to the article of Dr. Booker in this volume.

V. GENERAL PROPHYLAXIS.

There is no class of diseases in pediatrics in which so much can be done in the way of prevention as in those of the gastro-intestinal canal. So long as dentition and atmospheric heat *per se* were regarded as the great causative factors, the field of prophylaxis was limited. But a better understanding of the etiology brings with it possibilities in prevention which are almost without limit. Could proper prophylactic rules be carried out, these diseases would cease to be what they are now, the greatest scourge of infancy.

Prophylaxis must have regard—

1. **To the hygienic surroundings** of children and to all sanitary conditions in the cities,—cleaner streets, more open parks, and better sewerage. Although these are not strictly filth-diseases, yet filth certainly conduces to their development. In the tenement-homes and all institutions for infants there should be more air and sunlight, less crowding, greater cleanliness about the persons of children, frequent bathing, and proper care of diapers. These in summer should either be washed immediately, or thrown into a disinfectant solution. In case infants are sick with diarrhœa this latter plan should invariably be followed.*

In regard to dress, the tendency is to keep young infants too hot: this should be avoided; and, on the other hand, at the sea-shore or in the mountains, the opposite danger of insufficient clothing, especially night and morning, in summer hotels and boarding-houses where no fires are to be had.

City children should be sent to the country, wherever it is possible, for the months of July and August. Part of the benefit here is derived from the change of air, and a larger part from the pure milk, which we might almost say is possible in the hot season only in the country. Where a long stay is impossible, excursions for a day do much. Our fresh-air funds and sea-side homes have done more in New York to diminish the mortality from diarrhœal diseases than all our medicinal treatment; their importance and value cannot be over-estimated.

In a general way everything should be done that is possible to build up the general health of the infants.

---

* The necessity of proper disinfection in stools is illustrated by the following, which recently came under my notice.

In a country house to which children from the city, sick mainly with intestinal diseases, had been sent, there had been up to a certain date the most marked and uniform improvement in all the infants. The woman who washed the napkins was now taken sick, and before another could be obtained these were allowed to accumulate to the number of two or three hundred, in large tin cans which were placed in a small yard in the rear. In a day or two, with July heat, the stench from this source became very marked; but before this was appreciated or removed, within thirty-six hours two cases of genuine cholera infantum developed, proving fatal, a marasmus child died, with intestinal symptoms, and exacerbations occurred in several other diarrhœal cases which were previously improving.

The place was emptied for a few days, and thoroughly disinfected, and no further trouble occurred.

2. Foods and Feeding.—Maternal nursing should be encouraged by every possible means. No weaning should be done, if it can be avoided, during summer. Nothing is better established than the close relation existing between hand-feeding and diarrhœal diseases. This is not, however, because of the hand-feeding in itself, but because this feeding has been so ignorantly done. We have not space here to discuss the whole subject of hand-feeding; for this the reader is referred to Dr. Rotch's article in volume i., with almost all the views of which we are in hearty accord. The main points associated with the production of diarrhœal disease may be grouped under the heads of overfeeding, too frequent feeding, improper foods, and impure foods.

Overfeeding.—While it is certainly true that the majority of infants among the better classes who are nursed entirely by the mother are underfed, it is still more true that almost all hand-fed infants among all classes are greatly overfed. The following table is derived from weighing a number of healthy infants before and after nursing, when they were nursed at proper intervals, to see how much they actually got at a nursing; and by measuring the capacity of nearly forty infants' stomachs at the different ages, these being carefully distended just sufficiently to obliterate the rugæ.

AGE.	ONE FEEDING.	NUMBER OF FEEDINGS.	DAILY AMOUNT.
2 weeks	2 ounces.	8	16 ounces.
1 month	3 "	8	24 "
2 months	4 "	7	28 "
4 "	5 "	6	30 "
6 "	5½–6 "	6	33–36 "
9 "	7 –7½ "	5	35–38 "
12 "	8 –9 "	5	40–45 "

These figures may be taken as the proper amount for an average child. Very large, robust infants may require a little more, and small, delicate ones considerably less.

Overfeeding is to be particularly avoided in summer, and it is at this time that it is most likely to be done, especially during days of excessive heat, from the thirst occasioned by free perspiration. It is at such times an excellent rule with infants to diminish each meal by at least one-fourth, making up the deficiency with water, and to give water in small quantities between the feedings.* Children, like adults, require less food in very hot weather, but more water. Unless this rule is followed, infants cry from thirst and heat, and even those at the breast are likely to be given too much food.

---

* Under this last point I wish to call attention to an experience of Dr. David Little, of Rochester, New York, which he published in "The Transactions of the Medical Society of the State of New York" in 1884.

In an orphan asylum in his city where every previous summer had witnessed a number of deaths from diarrhœal disease, he directed that infants should be fed at three-hour intervals during the day and should have nothing at night. Water was allowed freely at all times.

The season passed without a fatal case from diarrhœal disease. At the close of the season he remarked to the Sister in charge that the new rules of feeding had proved beneficial. She replied, "*Yes, but it did seem rather cruel to feed the infants only three times a day.*" These were the directions as she had understood them and as they had been rigorously carried out.

Too Frequent Feeding.—This is usually an accompaniment of overfeeding, but not always. No more pernicious habit exists, and none more certain to set up gastro-intestinal disorder, than that of filling a large bottle with food and putting the nipple into the child's mouth while it lies in its crib or carriage, allowing it to sleep and eat alternately for the greater part of the time. The same can be said of the habit of allowing an infant to sleep at the mother's breast and nurse every time it wakens during the night,—often a dozen times.

If we would prevent gastro-intestinal disease we must attend to the hygiene and physiology of the stomach and intestines, and with these the taking of food into the stomach every hour or oftener is absolutely incompatible: there can be no such thing as healthy digestion.

Food in proper quantities, at proper intervals, with absolute regularity, and the stopping of night-feeding and nursing as early as possible, are the first essentials of healthy digestion, and fundamental principles in the prophylaxis of all intestinal diseases. We have emphasized these points, not because they are of greater importance than the one next to be discussed, but because they have been so often ignored, even when due care has been bestowed upon the selection and preparation of the artificial food.

Improper Foods.—The habitual use of improper articles of food is a very important predisposing cause of diarrhœal disease. Children thus fed suffer almost always from a mild intestinal catarrh.

Our experience leads us to the belief that no infant foods can compare with cow's milk for infants during the first year, and that the extensive use of all dextrin and starchy foods as substitutes during this period is to be deprecated. They do harm very often not so much from what they contain as from the elements they lack. Their direct agency in causing diarrhœal diseases has, however, we think, been rather overstated. Much more to be condemned is the miscellaneous feeding of infants with things from the table,—vegetables, meat, sweets, and other articles totally indigestible.

To be especially avoided during the second year are most vegetables, particularly beets, tomatoes, and potatoes, fruits, especially in cities and in summer, all dried fruits, all cakes and sweets, coffee, and tea. We have found no rules to avail much unless mothers are given a written list of articles allowed and forbidden during the second and third years.

In older children improper foods and feeding are not only the predisposing but in most cases the exciting causes also.

In summer stale and unripe fruits and melons should be avoided, also free indulgence in ice- and soda-water. The constant habit of lunching at all hours upon cakes, pies, candies, nuts, etc., should on no account be tolerated, nor the indulgence at meals in pastry, highly-seasoned entrées, soups, and jellies. The children in our American homes too often are allowed to make the principal part of their meals from such food, to the exclusion of plainer and simpler articles.

There is only one way to make children desire the proper articles, and that is to prohibit absolutely all others and give plenty of plain simple food at proper intervals.

Impure Foods.—First and pre-eminent under this head is milk, and most important are the changes induced in it by bacteria.

More important than all else in the prevention of diarrhœal diseases is it that rich and poor in city and in country should be supplied with pure and wholesome milk, and that they should be taught how to keep it so in their homes.

Care of cows: The stables must be clean and airy; the teats, udders, and milkers' hands must be carefully washed before milking. The cows must have open air and plenty of plain food. Milk from cows stuffed with garbage, brewery slops, etc., should not be used, nor from cows which have themselves evidence of disease on the udders or elsewhere.

Care and transportation of milk: The milk should be placed as soon as possible in tightly-covered vessels, and be disturbed as little as possible by pouring from one vessel into another. Until transported it should be kept at a temperature below 50° F. Transportation should be in refrigerator cars, and the milk should be inspected on its arrival in the city and its temperature taken. No milk should be admitted which registers over 60° F. The city delivery of milk, also, should be in carts in which the cans are kept upon ice during the summer months. The sale of milk, whether from wagons or from shops, should be allowed only by dealers licensed by boards of health, and the dealers should be compelled to keep milk at the proper temperature, about 50° F. Systematic milk-inspection should be kept up, and licenses revoked for violation of rules. None of the precautions now taken to secure against the dilution and adulteration of milk should be neglected.

The care of milk in the homes: It should not be delivered so early that it must stand two or three hours in pitchers, etc., before it is put on ice. For young children there is a great advantage here in the use of milk delivered in bottles. As soon as possible after it is received, the milk should be put into the bottles from which it is to be fed, in quantities proper for a single feeding. This practice should be followed also in the case of infants who are not fed from a bottle.

The milk is now to be sterilized, according to the directions given elsewhere in this work.

In institutions where it is impossible to sterilize all milk in separate feeding-bottles, the same thing can be accomplished with tolerable certainty by raising the milk to the boiling-point in a saucepan or a covered vessel, maintaining this temperature for thirty minutes, and then pouring it into quart bottles which have been the same length of time in boiling water, corking with cotton, and placing on ice. As an entire bottle can be used up for a single feeding of several children, there is not the objection of having to open the bottle several times before its contents are consumed.

Among the poor and negligent, where proper directions for sterilizing cannot be carried out, the best substitute seems to be to use the bottled milk, and keep the closed bottles in boiling water three-quarters of an hour, then put on ice.

The value of sterilizing milk before feeding it to infants is established beyond the necessity of discussion here. In cities, where some of the milk is twenty-four hours old when received, and forty-eight hours old when consumed, the need is imperative. In the country, where fresh milk can be obtained twice a day from healthy cows, the same necessity does not exist. But even there it is best to strain the milk through cotton and put it when received into the bottles from which it is to be fed, cork with cotton, and place on ice. If proper care is bestowed upon the cows, nothing more is required, beyond care of utensils.

The care of bottles, rubber nipples, etc., is second in importance only to that of the milk itself. The best method of cleansing bottles we have found to be the following. Rinse with cold water, carefully scrub with brush and hot suds, fill with weak soda solution and let stand till needed for milk supply, then boil for half an hour, or bake for the same length of time in a hot oven, and cork with cotton.

The use of long rubber tubes, or tubes of rubber and glass, as attachments for feeding-bottles, should never under any circumstances be allowed. To keep these clean is almost a matter of impossibility, even for the most careful. They are held in high esteem among the poor, since when they are used an infant can be placed in its crib, the nipple put in its mouth, and the child left to sleep or eat as it wills, for hours at a time; while the other style of nipple needs the attention of some one until the meal is finished, to keep the bottle tipped so that the milk will flow.

Only rubber nipples which slip over the mouth of bottles should be used. These should be turned inside out and scrubbed at least once a day, and at all times when not in use should be kept in a solution of borax or salicylate of sodium.

What has been said of milk applies with equal force to all milk foods, gruels, broths, and infant-foods generally. Only water which has been boiled at least half an hour should be used in their preparation. Everything left over from a single feeding should be thrown away, no warmed-over messes being given. Under no circumstances should milk or any food be allowed to stand in open vessels in a living-room.

The entrance of germs into the canal is to be prevented not only by destroying by heat all those existing in milk and other foods, but also by boiling all water given to the child, by attention to the cleanliness of the child's mouth, as well as of its hands, which so much of the time are in the mouth, and, in the case of nursing infants, by cleanliness of the mother's breast and nipples; these should be washed before and after each nursing.

Another important point in the prophylaxis of severe forms of disease is early and prompt attention to all the milder derangements of the stomach and intestines, particularly during summer. The larger proportion of cases of cholera infantum and entero-colitis are preceded for some time by milder symptoms. Prompt attention at the outset is usually efficient. Too much cannot be said in condemnation of the practice of allowing a slight looseness of the bowels to go on for a week or more, simply because the child happens to be teething. Yet many mothers believe such a condition of the bowels to be not only not injurious but even positively beneficial. Such an error has cost many infants' lives.

Every gastro-intestinal derangement, no matter how slight, should receive prompt attention, with the idea that at any time severe and even dangerous symptoms may supervene.

To summarize, prophylaxis demands,—

1. Getting as many infants out of the city in summer as possible.
2. The education of the laity up to the importance of regularity in feeding, to the dangers of overfeeding, and as to what is a proper diet for infants just weaned.
3. Proper legal restrictions regarding the transportation and sale of milk.
4. The exclusion of germs or their destruction in all foods given, but especially in milk, by carefully sterilizing milk, and scrupulous cleanliness in bottles, nipples, etc.
5. Prompt attention to all mild derangements, especially in summer.
6. Cutting down the amount of food and increasing the amount of water during the days of excessive summer heat.

VI. SIMPLE DIARRHŒA.

Under this head it is meant to include those cases of diarrhœa in which there is a derangement of function without anatomical changes, without fever, and without involvement of the stomach,—*i.e.*, which are not dyspeptic. With these limitations the number of cases to be included under this head is very much smaller than most writers upon the subject describe.

Etiology.—Predisposition is the same for this as for all other varieties of diarrhœa,—age (under two years), bad intestinal hygiene, such as bad habits of feeding and improper food, insanitary surroundings, and the warm season.

The most important special causes of this variety are those acting upon the nervous system. As such may be classed dentition, chilling of the surface, exhaustion from fatigue or other cause, and the direct effects of atmospheric heat. The last two mentioned—exhaustion and heat—are very much more frequently associated with dyspeptic diarrhœa, yet there seems to be pretty good ground for the opinion that this is not always the case. The same may be said of menstruation and various nervous impressions upon the mother of a nursing infant.

Foreign bodies, or articles of food which act virtually as foreign bodies, such as uncooked or partly-cooked grains of rice, hominy, barley, or green corn, or green fruits,—and nuts and raisins in the case of very young children,—all these may be the cause of a simple diarrhœa. These cases are sometimes classed as instances of mechanical diarrhœa.

Certain fruits, such as the peach, pear, grape, etc., may excite diarrhœa, from the organic acids they contain or from their seeds acting mechanically.

Diarrhœa may be due to any one of the various cathartic drugs, in which the normal physiological effects have, from the susceptibility of the patient, been very greatly exaggerated in intensity or prolonged. It is extremely doubtful if any of the ordinary cathartics given to the mother ever operates upon the child's bowels through the milk.

A hypersecretion of bile is generally believed to be sometimes a cause of diarrhœa. Such cases are certainly rare.

The common habit in this country of allowing children to drink freely of ice-water may result in an attack of diarrhœa, apart from another visible cause.

Pathology.—In these cases we have neither intestinal decomposition nor intestinal inflammation as the cause of the symptoms. There is increased peristalsis, depending upon local irritation or of reflex origin, increased secretion, chiefly serous, and in most cases a moderate hyperæmia; this is sometimes, judging from the symptoms, pretty intense. If the exciting cause continues operative, the case may go on to intestinal inflammation.

Symptoms.—These may come on suddenly or gradually. If suddenly, there is usually abdominal pain preceding the diarrhœa; otherwise this is absent. There are at first one or two soft, fæcal stools; then they become quite thin, and may be watery. There may be as many as eight or ten in a day. There may be restlessness in the case of infants, and at all times there is a good deal of exhaustion, and often a clammy skin from perspiration. But there is no vomiting, and the temperature is not elevated, these two negative symptoms quieting at once the apprehension that may have been felt regarding a more serious illness. The stools are not often green in infants, but are of a pale-yellow or gray color; in older children they are thin and brown or gray, and in all there is more or less odor. If the cause has been some material acting as a foreign body, this may be found in the discharges.

If left to themselves, these cases usually recover in three or four days, but they may also develop into more serious forms of intestinal disease, particularly if it be summer. If the cause is not removed, there may be frequently recurring attacks such as have been described, until a chronic diarrhœa is finally established.

Treatment.—These cases in the vast majority of instances are easily and promptly curable if taken in season. Opium is the sovereign remedy; but before this is given a full dose of castor oil should be administered. A teaspoonful may be given to an infant of from three to six months, a tablespoonful to a child over four years. If the cause of the diarrhœa is any mechanical irritation, this preliminary cathartic is an absolute necessity. It is a good rule in all cases. Calomel (gr. i to gr. iii) or syrup of rhubarb (ʒi to ʒiv) may be substituted for the oil, but they are less certain and less satisfactory. Five or six hours after the cathartic the opiate should be given. It is a good rule to prescribe a safe dose and order it to be repeated after each stool. The form of preparation is not of great importance: paregoric and Dover's powder are probably as good as any. For a child a year old from six to ten drops of the former or a quarter of a grain of Dover's powder may be ordered in the manner indicated. Opium stops peristalsis, and after the intestine has been emptied that is mainly what is wanted in these cases.

In cases not yielding promptly to opium alone, bismuth subnitrate may be added, but this will not often be required. The child must be kept quiet in its crib or carriage, and on no account be allowed to run about until it is quite well.

In the matter of diet almost nothing must be given for twelve to twenty-four hours, and then for two or three days only food which can be almost entirely absorbed. The point is to keep the intestines as quiet as possible until the irritation has subsided. Barley-water, thin broth, and whey may be used, but no milk, unless it be breast-milk. Careful feeding must be kept up for a week, to prevent a recurrence of the diarrhœa. If it is summer, this is imperative.

A proper management of these cases of simple diarrhœa is one of the most important prophylactic measures against the severer forms of intestinal disease. On no account should these cases be neglected because the child happens to be teething.

VII. ACUTE MYCOTIC DIARRHŒA, OR DIARRHŒA OF BACTERIAL ORIGIN.

Synonymes.—Acute gastro-intestinal catarrh, Cholera infantum, Summer complaint, Summer diarrhœa, Infectious diarrhœa.

It has seemed to me that our knowledge of this class of cases has advanced far enough to make a change from the time-honored "summer diarrhœa" not only justifiable but even necessary. It should be kept before our minds constantly that the most potent factors in producing this disease—or, rather, these diseases—are micro-organisms. The grounds upon which this opinion rests have been already gone over pretty fully in the section on the relation of bacteria to diarrhœal disease.

The lesions have been described under the heading of acute desquamative catarrh. It has seemed to me that the clearest understanding of these cases is reached by considering the process as not exactly inflammatory, but rather an acute decomposition or fermentation in the gastro-intestinal tract which is preliminary to inflammatory lesions.

Two distinct forms are met with: (1) acute dyspeptic diarrhœa; (2) cholera infantum.

I. ACUTE DYSPEPTIC DIARRHŒA.

Etiology.—All the causes enumerated in the section on etiology are important here. This variety includes the greater number of the cases of summer diarrhœa, or at least forms a stage in these cases. It is most frequently the initial stage, but it is sometimes the final one. We need not do more here than summarize the causes summer heat, artificial feeding, bad habits of feeding, improper foods, impure milk, bad surroundings, and city residence, as the etiological factors.

Pathology.—Dyspeptic diarrhœa is a diarrhœa set up by undigested food in the intestine and by the putrefactive changes in such food. If the resistance of the patient is great, the cause a transient one, and the case properly managed, there is only functional disorder, and in a few days there may be complete recovery. In a susceptible patient, where the exciting cause continues operative, or when improperly managed, the process continues, and anatomical changes are produced,—*i.e.*, the case becomes one of gastro-entero-colitis in which the dyspeptic diarrhœa was the initial stage.

Symptoms.—Two forms are met with: first, a mild form, with a gradual onset, with little or no fever, and usually without any gastric disturbance; secondly, a severe form, in which the onset is sudden, usually attended by high temperature and by vomiting.

In the mild form there may be for the first few days no symptoms except the diarrhœal discharges, or the child may be peevish, fretful, especially so at night, and may seem generally out of sorts. From the fact that the general symptoms are so few, cases of this kind are often allowed to go on for several days by mothers under the common belief that the children are "only teething."

The stools are green or yellow, thinner than normal, and contain masses of undigested fat and occasionally curds. Sometimes they are of an offensive odor, but frequently not; there are usually from three to six daily. After a few days they contain in most cases mucus in smaller or larger quantities. Fruits or starchy foods appear in the stools almost unchanged. The appetite may be normal, but is usually impaired, and may be almost lost after a few days. The tongue shows generally a thin white coating; the mucous membrane of the mouth may be congested, or in very young infants covered with thrush. Sometimes the general health will not be noticeably affected for two or three weeks. Often after a few days the infants become pale, lose flesh, their limbs become soft and flabby, they lose their spirits, and the scales show a loss of one or two pounds in a week. If proper treatment is instituted and the cause is removed, there is noticed an improvement in the character and frequency of the stools, the mucus disappears, the color becomes a pale yellowish green and finally yellow, the appetite returns, the strength and spirits improve, and the children recover after an illness of from four to fourteen days. Occasionally the condition may last for a longer time. It is very common to have an occasional bad stool after these have been generally good for a day or two, but this is of no significance. Relapses are very easily brought on by slight irregularities in diet, especially overfeeding. In the cases which do not run this favorable course we may have at any time the supervention of acute severe symptoms, and the case may become one either of cholera infantum or of entero-colitis. This change often takes place with great suddenness, and is frequently coincident with a few days of very hot weather or follows some gross dietetic error.

A third termination, but not so common as either of the preceding, is a continuance of the mild symptoms with exacerbations and remissions during the entire summer season, until the cool weather of autumn comes.

These cases may be cut off at any time by any intercurrent disease, particularly by pneumonia.

Infants suffering from athrepsia not uncommonly die from a very slight exacerbation of the intestinal symptoms, the autopsies revealing no other cause of death.

In the cases developing suddenly the clinical picture is quite a different one. The attack may begin abruptly in a child apparently healthy, or there may have been for some days symptoms of slight intestinal derangement. If an infant, it is restless, cries much, sleeps but a few minutes at a time, and seems in distress. The skin is hot and dry, the temperature runs up rapidly to 102° or 103° F., often to 105°, the abdomen is distended and hard, the legs are usually drawn up, and all the symptoms indicate the onset of some grave disorder. The nervous symptoms in some cases are very severe, and even convulsions may occur. There may be great thirst, so that everything offered is taken eagerly, or, on the other hand, everything may be refused.

Usually in the course of from four to six hours after the onset the gastro-intestinal symptoms come on. There is first vomiting, which may be of undigested food taken many hours before. If this was milk it frequently comes up in hard curds and very sour. After the stomach has been apparently emptied, mucus and serum are ejected in small quantities after much retching, and sometimes the vomiting is bilious. The vomiting is easily excited by the giving of food or drink.

Diarrhœa soon follows,—first feculent stools, then great bursts of flatus, with the expulsion of very thin yellowish stools of a terribly offensive odor. Four or five such discharges may occur in as many hours. In other cases the stools are gray, green, or greenish yellow, sometimes brown; but characteristic features are the amount of gas expelled, the colicky pains preceding the discharges, and the sickening odor.

In a considerable number of the cases this free evacuation of the bowels is followed by a fall in the temperature and subsidence of the nervous symptoms, and the child falls asleep, to be awakened for an occasional stool after a few hours.

The prostration is often great in the beginning, but not of long duration. Under favorable circumstances and with proper management, the case, after twenty-four or thirty-six hours of severe symptoms, may go on to a rapid convalescence. The movements continue abnormally frequent for three or four days, but gradually assume their normal character, and a prompt recovery can usually be predicted.

Such are the cases in which the brilliant results of treatment are obtained, and often reported as cures of "cholera infantum." The chief features contributing to such favorable results are a good constitution on the part of the child and the ability to regulate the feeding afterwards.

If circumstances are not so favorable, if the child is cachectic and badly cared for, the fall in the temperature is often only a temporary one; the vomiting may not recur, but the diarrhœa keeps up, the stools gradually changing in character, becoming less offensive perhaps and not so fluid, but with mucus added and occasionally streaked with blood; in other words, becoming more and more of the character seen in entero-colitis.

The general symptoms follow the same course: the first profound impression made upon the nervous system subsides, and the children become pale, worn, prostrated, and exhibit the symptoms described in the section on entero-colitis.

In some cases there may be a series of such attacks separated by a week or ten days, the stools never becoming quite normal between them, but all other symptoms being absent. It may be not until the third or fourth attack that the entero-colitis is finally established.

In children over two years old there are some features which differ from the cases described above as occurring in infants.

Here they usually follow the ingestion of some indigestible article of food, such as green apples, unripe berries, etc., or milk which has been tainted from exposure. Vomiting here does not come on so readily as in infants, pain is a much more prominent feature, and the temperature is, as a rule, lower.

Such cases, although beginning with severe symptoms, usually make good recoveries: there is much less likelihood of their running on to inflammatory forms of diarrhœal disease than in the case of infants.

Diagnosis.—The diagnostic points about the acute attacks are their sudden onset, their severe symptoms, their brief duration, and usually their favorable termination. They are violent, often alarming, but brief, convalescence frequently being established in two or three days.

Dyspeptic diarrhœa is to be differentiated from cholera infantum and gastro-enteritis or entero-colitis, and in its onset from the general diseases malaria, scarlatina, pneumonia, and tonsillitis.

From cholera infantum it is distinguished by its milder character,—prostration being less, temperature usually lower, nervous symptoms less pronounced,—but particularly by the stools: the large serous neutral or alkaline stools belong only to cholera infantum. Although nearly every case of cholera infantum is preceded by a dyspeptic diarrhœa of greater or less severity, the former is not to be regarded as simply a more severe form of acute dyspeptic diarrhœa.

To differentiate these cases from those of inflammatory diarrhœa is impossible for the first day or so. The onset is often identical, and we cannot say at once whether they are going on to the development of inflammatory changes or not. The subsidence of fever and all severe symptoms at the end of twenty-four or thirty-six hours shows that we have had only a putrefactive process with functional derangement; while a continuance of severe symptoms, and especially of the fever beyond the second day, is usually evidence of inflammatory changes.

The sudden development of high fever, prostration, vomiting, and even diarrhœa, is common to very many diseases of infancy, especially to malaria, pneumonia, scarlatina, and tonsillitis. It is always difficult, and very often impossible, to say at the outset whether we have anything more than a dyspeptic attack to deal with. The symptoms of the latter are often so severe that it is difficult to believe the sole cause to be the gastro-intestinal disorder.

Tonsillitis is revealed by an inspection of the throat. Before excluding scarlatina we must wait until the time for the rash. The question of malaria is a difficult one to decide, and may require an observation of the temperature for two or three days. Pneumonia can usually be recognized by the physical signs, if it is looked for.

In general, marked improvement in the gastro-intestinal symptoms with a continuance of the general ones—fever, prostration, etc.—drives us to seek another explanation for them. More than once I have seen pneumonia overlooked until the third or fourth day because of the early prominence of gastro-intestinal symptoms.

It should be remembered that any acute disease in summer is likely to present gastro-intestinal symptoms, especially at its onset.

Prognosis.—There are very few cases of acute dyspeptic diarrhœa that prove fatal, except among children already suffering from athrepsia. It is not uncommon among such children in institutions to have fatal cases of diarrhœa which have never presented any choleraic symptoms, and which do not show at autopsy the lesions of entero-colitis. The explanation seems to be that such feeble constitutions are overcome in the first stages of intoxication and prostration. It is a surprise to see with how few symptoms such children succumb.

In all cases suffering from athrepsia any diarrhœal attack may prove fatal, and a guarded prognosis must be given.

In other cases our prognosis resolves itself into this question: what are the probabilities that the existing attack will go on to the development of inflammatory changes?—*i.e.*, will it become a gastro-entero-colitis, or an entero-colitis? In answering this there must be considered the child's constitution, the manner in which it has been fed, the previous state of its gastro-intestinal canal, its surroundings, how early the case comes to hand for treatment, and how well treatment can be carried out. If the child has been rather delicate, has been badly fed, has suffered from frequent previous indigestion and mild diarrhœa, if its surroundings are bad, if the attack has been allowed to run on two or three days before interference, and if proper dietetic and hygienic treatment cannot be carried out,—all these circumstances make it likely that the attack will become an entero-colitis, and the likelihood is generally just in proportion to the number of the factors which are present.

Manifestly, all these conditions are worse in very hot summer weather.

Much depends, then, upon early energetic treatment and one's ability to remove the exciting causes. The prognosis is worse in patients suffering from previous disease, such as pertussis or pneumonia.

Complications.—The complications are mainly thrush, seen mostly in very young infants, and erythema of the buttocks and thighs. Both of these are referred to in detail under entero-colitis.

Treatment of Dyspeptic Diarrhœa.—The subject of prophylaxis has been discussed at length in the general chapter upon that subject. Almost everything there said will apply to the cases under discussion.

HYGIENIC TREATMENT.—If the attack occurs in summer and does not yield at once to the management employed, *a change of air* should be made, wherever it is possible. Whether the child be sent from the city to the seashore or to the mountains is not so important as it is that it shall go where it will be likely to have the best food and the best local surroundings. A change is the main thing. In the country or in small towns a change is not so necessary, and, in fact, is not generally required unless the condition becomes somewhat chronic. In such cases more can sometimes be accomplished by a change of air than by all other means.

Among the tenement-house children of New York much good is done by the day excursions upon the salt water. Too often, however, only temporary benefit results, and the cases relapse on their return to their homes.

Fresh air is of the utmost importance to all diarrhœal cases in summer. No matter how much fever or prostration there may be, these cases always do better if they are kept out of doors, except possibly during three or four hours in the middle of the day on very hot days. Nothing is so depressing as close, stifling apartments. Children should not be allowed to walk, even if they are old enough and strong enough to do so. They can be kept out in carriages, in perambulators, or in hammocks. Quiet is also important.

The *clothing* in summer should be the lightest flannel to be obtained: a single loose garment is preferable. A thin layer of linen or muslin can be put next the skin where there are much perspiration and a sensitive skin.

At the sea-shore and in the mountains especial care should be taken to see that sufficient clothing at night is supplied.

Bathing is of very great advantage to allay restlessness, as well as for cleanliness and the reduction of temperature. For the first purpose a sponge-bath of alcohol-and-water or vinegar-and-water is sufficient. For the reduction of temperature only the tub-bath is to be relied on. If the temperature continues above 102° F. or near that point, systematic bathing must be carried on. The temperature of the bath should be nearly 100° F. when the child is put into it, and should then be gradually reduced to 80° or 85° by adding ice. The bath should be continued for from ten to thirty minutes, according to the amount of reduction effected, and repeated from two to eight times daily, according to the requirements of the case. The bath thus used has generally a very quieting effect, which would be entirely lost by the terror and excitement caused by putting an infant suddenly into a cold bath.

Scrupulous cleanliness should be secured in the child's person and clothing. Napkins should be removed from the child and from the room as soon as soiled, and placed in a disinfectant solution. Frequent washing of the buttocks and genitals, together with the irritation from the discharges, often causes excoriations. If these exist, plain water should not be used for bathing, but bran-water should be substituted.

Dietetic Treatment.—Dietetic and hygienic treatment in this class of diarrhœas is of very much more importance than the use of drugs. It is of the first importance to remember that during the stage of acute febrile symptoms digestion is practically arrested. To give food requiring much digestion, manifestly, can do only harm. In the stomach it produces irritation until it is expelled by vomiting or passes into the intestine and adds to the fermenting masses there present and aggravates the existing disorder.

In nursing infants the breast must be withheld so long as a disposition to vomit continues, and no food whatever given for from six to twelve hours. Thirst may be allayed by rice-, barley-, or toast-water or mineral waters given cold and frequently but in minute quantities. Stimulants may be added to these if required. If these are refused or vomited, absolute rest to the stomach will do more than anything else to hasten recovery. After the stomach has been quiet for ten or twelve hours it is generally safe to allow the child to be put to the breast, tentatively. The intervals of nursing should not be shorter than three hours, and the amount allowed at one feeding should not be more than one-half or one-third the usual meal. The remainder may be made up by mutton or chicken broth or by thin barley gruel. The amount of breast-milk allowed may be steadily increased, so that in three or four days the breast may be taken exclusively. If there is any reason to suspect the breast-milk as a cause of the attack, such as menstruation, pregnancy, or some nervous influence—exhaustion, grief, or fright—on the part of the nurse, we must stop the nursing temporarily or permanently, according to circumstances, and secure a wet-nurse or begin hand-feeding.

In infants just weaned the same plan is to be followed and a return to the breast made if possible.

In young infants who are being hand-fed, if the attack be a severe one and in summer, a wet-nurse should be secured wherever this is possible. In case a wet-nurse is out of the question, we are brought face to face with one of the most difficult problems in the management of diarrhœa: how to feed artificially a young infant suffering from dyspeptic diarrhœa, either acute or subacute.

When the exact nature of these dyspeptic diarrhœas is better understood, when the life-history of the various forms of bacteria which set up putrefactive processes is known, and we are able to say from clinical symptoms which process we are dealing with in a particular case, we may approach to something like scientific accuracy in our dietetic treatment. But until that time comes we must be guided by experience alone.*

First, as to the use of cow's milk. While nursing infants should generally be put back upon the breast as soon as vomiting is permanently controlled, it will not do to follow the same rule with respect to cow's milk. This must generally be withheld in all forms until all acute symptoms are past. The experience of the profession is nearly unanimous upon this point. Our reliance at this stage is upon egg-water,† the animal broths,‡—chicken, mutton, and beef,—the expressed juice § of beefsteak, beef peptonoids,‖

---

* Escherich,[32] from his bacteriological studies, has laid down the following rules for feeding, the practical value of which has not yet been proved, but which seem worthy of a careful trial. If albuminous decomposition with very foul, offensive stools exists, these articles should be withheld from the diet and carbohydrates given, dextrin foods, sugars, etc.; if an acid fermentation is present, with sour but not offensive stools, carbohydrates are to be withheld, and albuminous foods given, such as animal broths, peptones, etc. Milk he classifies with the carbohydrates, since in its decomposition it is the sugar of milk and not the casein that is usually broken up.

Baginsky[33] has followed out this plan of feeding, but did not find it satisfactory, the character of the stools not being a sufficient guide to the nature of the process in the intestine.

† *Egg-Water.*—The white of a fresh egg, a pint of cold water (previously boiled), a teaspoonful of brandy, and a small pinch of salt.

‡ *Animal Broths.*—One pound of finely-chopped *lean* meat (chicken, mutton, or beef), one pint of cold water (one and a half pints for young infants); put in a glass jar, and let stand four to six hours on ice, covered. Cook three hours in a closed jar over a slow fire, strain, cool, skim off fat if any rises, season with salt, and feed warm or cold. It may be cleared with egg if desired.

§ *Beef Juice.*—Thick steak, broiled rare, juice pressed out with meat- or lemon-squeezer, season.

‖ Of the beef peptonoids sold in the market, Carnrick's liquid preparation is usually easiest given and best borne. Of the various meat extracts, Rudisch's "sarcopeptones."

barley- and rice-water, and the dextrin foods, such as Liebig's, Horlick's, or Mellin's, made without milk, or "flour ball" * and water, or wine whey.†

After the first two or three days, when the symptoms of acute fermentation have subsided and the stools are less frequent, we may add cow's milk to the diet, tentatively. It is not enough that milk be sterilized, for this procedure, although of very great value as a prophylactic measure, has but little curative value.

There are three methods of administering milk. The first is by free dilution,—at least four parts of plain water or barley-water to one of milk; in many cases milk given in this way will be found to agree perfectly, and nothing more will be required. As the case progresses, the proportion of milk can gradually be increased. The second is the well-known method of partial peptonization by the use of Fairchild's tubes, the process being continued from six to fifteen minutes, and not allowed to go on to develop the bitter taste. With this I have been very frequently disappointed. It has failed much more often than it has succeeded.

The third method is the same process continued for *two hours*, at the end of which time all the casein has been digested. Lemon-juice can now be added to cover up the bitter taste, without causing any curd; and with the addition of a little sugar a very palatable food is produced. It is readily taken, all the more so usually from its sour taste. I have used it with the happiest results. It certainly deserves more attention than it has received.

With milk, as with every other food, its effect upon the character of the stools must be our guide in its use.

Some of the forms of fermented milk, such as koumys, kéfir, and matzoon, serve a very useful purpose, and can often be retained upon an irritable stomach when almost everything else is vomited. Young infants will usually take them eagerly at first, but soon tire of them and finally refuse them altogether.

In the diarrhœas of older children which have for their most common cause the too early use of solid food or the use of improper articles of food, nothing succeeds so well in most cases as a milk diet. The milk should be boiled, and one-third lime-water added at first. Everything in the shape of food is, of course, to be withheld while there exists an inclination to vomit.

General Rules regarding Feeding.—No food whatever is to be given upon a very irritable stomach. Articles requiring the least digestion and leaving the smallest residue should next be tried. Food prescriptions must be made with the same care and exactness as prescriptions for drugs; for in most cases they are more important. Quantity and frequency must be definitely stated, as well as the articles ordered. Directions should be given in writing, or they will be half forgotten before the physician is out of the house.

---

* *Flour Ball.*—Two or three pounds of wheat flour, tied in a bag and boiled continuously for twelve hours; the outer shell is scraped off, and the inner, yellow portion (mainly dextrin) grated and used to make a thin gruel.

† *Wine Whey.*—A teaspoonful of wine of pepsin, one pint of milk at a temperature of 110° to 120° F.; let stand till firmly coagulated. Break up curd and strain. Add sherry wine in proportion of one to four or one to six. Feed cold.

A practical acquaintance with the proper appearance and taste of every food ordered is absolutely indispensable.

There are four common mistakes in feeding in diarrhœa which are the cause of many a failure: feeding too much at a time, feeding too frequently, trying too many articles at once, and changing before a thing has been really tested.

For a single feeding the quantity allowed will vary according to the tolerance of the stomach; but it should always be much less than is given in health, usually from one-fourth to one-half that amount until the child demonstrates his capacity to digest more. It is rarely necessary to nurse or feed a sick child oftener than every two hours. Of course, in cases of great prostration stimulants may be required much more frequently. We have only to imagine how an adult with a sick stomach would feel to be offered something in the shape of food every five or ten minutes, in order to appreciate the disgust for all food which soon overtakes an infant who is similarly besieged.

By trying four or five articles at once and changing the diet every day or oftener, the list is soon exhausted, and it is impossible to say which of the articles was at fault.

Still, after all has been said, it is a difficult problem to feed these children under three years of age, capricious as they are by nature and still more so by education; and the judgment and tact of the physician are taxed to their utmost. We must have many resources; for a diet which one child takes well, the next disdains utterly. The best method is to select from a list of articles of accepted value such as circumstances will permit, and such as are most likely to be properly prepared, and try them patiently, one after another, until one is found which the child under treatment will take and which agrees with him.

Medicinal Treatment.—In these cases it must be borne in mind that we are not treating an intestinal inflammation, although such may be the ultimate result of the process beginning as a dyspeptic diarrhœa. Essentially here our treatment is to be directed against the process of fermentation or putrefaction, and towards the restoration of the normal gastro-intestinal functions which have been deranged.

The indications are (1) to evacuate the fermenting masses from the stomach and intestine; (2) to combat the process of decomposition by drugs and proper food; (3) to restore healthy action by intestinal hygiene; (4) to treat symptoms and complications.

It is not often in acute cases that we are obliged to resort to therapeutic measures to empty the stomach, as the vomiting is usually sufficient for that end. In cases of continued retching, where but little is ejected, it may be that larger curds than can be easily got rid of are present. Emetics, although they serve a very useful purpose in older children, are not to be advised in young infants.

In such cases the best and most certain measure is to wash out the stomach. In acute cases I think its use should be limited to those of uncontrollable vomiting. The largest size of flexible rubber catheter is the best instrument, and plain lukewarm water probably the best fluid. The water is allowed to flow in and out freely until it comes away quite clear. Stomach-washing may be practised without danger in the youngest infants. It is a simple procedure: in fact, it is exceedingly difficult to pass the catheter anywhere else than into the œsophagus, as any one familiar with intubation will appreciate. A single washing in most cases is all that is required. It is never necessary to repeat it more than once daily. In certain cases this is probably of more value than all else.

After the stomach has been emptied, a small quantity of some medicinal solution may be left in the organ if desired. In Germany those most employed are a three-per-cent. solution of benzoate of sodium and a half-per-cent. solution of resorcin. No food whatever is given for two to four hours, and then only the blandest articles in small quantities.

Stomach-washing has long been in use in Germany, but has not yet been so much employed in this country as it deserves to be. It is not in the class of cases under discussion that its greatest value is seen. From personal experience I am led to think highly of it. (For a full account of the literature of the subject see the articles of Ehring[34] and Epstein.[35])

As a substitute for stomach-washing, some writers have advocated the practice of allowing infants to drink freely of fluids, especially ice-water, which is generally taken readily, although almost immediately vomited. This seems a very uncertain way of doing what can be so much better done by stomach-washing. It certainly acts in many cases to intensify and aggravate the irritability of the organ.

To empty the intestines is an indication in every instance, no matter whether or not any indigestible food has been taken. This may be accomplished by cathartics or by intestinal irrigation.

Of the cathartics, castor oil and calomel are greatly superior to all others. Calomel has the advantages of ease of administration, of its favorable effect upon vomiting, and of its antifermentative as well as purgative action. One or two grains of the tablet triturates given dry upon the tongue are sufficient for a child under two years. Unless the stomach is upset, I prefer castor oil in most cases, as it sweeps the whole canal, causes little griping, is very certain, and its after-effects are constipating. A child over a year old ought to take two teaspoonfuls, which may be given clear with a few drops of brandy dropped over it, or in an emulsion. It is not often vomited when given plain. To older children it may be given suspended in soda-water with some syrup of orange or sarsaparilla. It is important that a full dose be given. The initial cathartic dose of oil, almost complete abstinence for twenty-four hours, and very careful feeding after that time, suffice to cure a very considerable proportion of these cases.

Only cathartics can be employed to evacuate the small intestine, while for the colon we may use, in addition or instead,—

Irrigation of the Intestine.—This has been now so long practised, both in this country and in Germany, that its value is well established. To be effectual, the water must reach the ileo-cæcal valve: it cannot be expected to do more. Attention to detail is necessary for success. The infant is placed upon the back, with hips elevated, and the water introduced through the largest size of a flexible rubber catheter or a rubber rectal tube of the same size, which is passed into the colon,—if possible, beyond the sigmoid flexure, as in that case the intestine above is readily filled. At least eight inches should be introduced. The catheter is attached to the nozzle of a fountain syringe, the bag of which is held three or four feet above the patient. During the introduction the water should be allowed to flow, as thus the intestine is distended a little in advance of the catheter, which greatly facilitates the process. The passage of the water into the colon high up is also aided by abdominal manipulation. To be certain that the water has reached to the cæcum we must have at least a pint in the colon at once for a child of six months, and a quart for a child two years old. (This I have found from experiments on the cadaver.)

We can usually see the outline of the colon when distended. Difficulty is experienced in certain cases in getting any considerable amount of water into the intestine at once. This is generally because the catheter has not been carried high enough into the intestine. Pressing the folds of the buttocks together is usually sufficient to secure retention. If not, a bandage rolled round the catheter until a roller is formed an inch and a half in diameter makes a good obturator when pressed against the anus.

Irrigations need not be repeated frequently, once in twenty-four hours—or twice, at most—being sufficient, provided they have been thoroughly made. They should be made by the physician, or at least under his personal supervision.

All sorts of solutions have been used. Carbolic acid should never be employed in any strength, from the danger of poisoning. I have known of one death from this cause. Bichloride solutions are of doubtful advantage. Here, as in the case of the stomach, it is the amount of fluid injected, not the character of it, that is important. The object is to flush the large intestine (as one washes out an abscess) thoroughly. At least a gallon should be used for a single irrigation, it being allowed to flow in and out till it comes away almost clear. It may be returned through the tube or alongside of it.

As the intestine is not, like the stomach, accustomed to plain water, a normal salt solution of one drachm to a pint of boiled water is less irritating, and should be preferred. If there is an abundant secretion of rather thick mucus, a solution of borax of the same strength may with advantage be substituted for the saline solution.

The injection of astringent solutions is not called for in acute dyspeptic diarrhœa. They will be referred to under entero-colitis.

The temperature of fluids used for injection is still a matter of discussion, some writers preferring ice-water, others water at 70° or 80° F., still others preferring lukewarm water. My own preference is for the medium temperature, except in cases where there is very high fever, when the colder solutions have a decided advantage. They should be allowed to flow out freely.

Antiseptic Drugs.—Since the recognition of the fact that putrefactive processes are at the bottom of this class of diarrhœas, the drift of opinion and practice has been towards the use of drugs which check the growth of bacteria. Almost every drug which is known to possess such power has been advocated in some quarter. Most of these have been used empirically, without any careful consideration of the nature of the fermentation going on in the particular case in which they were given, and ignoring the fact that any other process than that of fermentation existed in the intestine. Hence, as we might expect, disappointment in results has followed.

What may reasonably be expected of antiseptics? Those which are freely soluble are not likely to do more than affect the stomach and the upper portion of the small intestine. Those which are slightly soluble may affect the stomach and the greater part of the small intestine. Only insoluble drugs can be depended upon to reach the large intestine in any considerable quantity.

It would be of great practical assistance in therapeutics to know not only the nature of the putrefactive process, but also where it is most actively going on. The symptoms indicate that it usually begins in the stomach,—*i.e.*, epigastric pain, distention, and vomiting before diarrhœa and intestinal symptoms. This is what might be expected in case the exciting cause were introduced with the food, which we believe to be usually the fact. There seems to be a direct extension from above downward, as bacteria and decomposing masses are carried along by the peristaltic movements of the intestine. I have found in autopsies upon diarrhœal cases that comparatively few bacteria are present in or upon the mucous membrane of the jejunum; and Escherich found in health that normal bacteria are scanty in the upper part of the small intestine, while very numerous below. The explanation he believes to be the very rapid peristalsis and abundant secretion of this part of the intestine. Nothnagel, from careful experiments, estimates that in health only two hours are required for a substance to traverse the small intestine. We know that in disease both peristalsis and secretion are usually very much increased. These seem to sweep the contents of the upper intestine, including bacteria, into the lower part of the canal; and here it is—in the lower ileum and the colon—that the most active and continuous decomposition is going on. Further support on this point is given by the fact that in entero-colitis the lesions are usually limited to the lower ileum and the colon.

A consideration of these points shows why so many antiseptic drugs advocated at first enthusiastically have been found with a larger experience to be worthless, because they probably never reached the seat of trouble.

The drugs which can be relied upon to influence decomposition in the lower ileum and the colon must be insoluble, and must be capable of being administered in large doses. Those which have this reputation are naphthalin and bismuth.

Naphthalin may be given in two- to four-grain doses hourly, either in suspension or rubbed up with sugar dry upon the tongue. While the taste is not disagreeable, the odor is intensely so. After thorough trial, I have discarded it. Although it does seem to possess a certain degree of value, it is greatly inferior to bismuth. In the proportion of one to two hundred, both Baginsky[33] and Vaughan[13] found it valueless outside the body in restraining putrefaction.

Bismuth has the advantages of ease of administration, and of possessing astringent as well as antiseptic properties. The salicylate has been lately brought to notice again by Escherich and Ehring, but to my mind it is greatly inferior to the subnitrate, chiefly because of the very much smaller doses (gr. i to gr. iv) in which it must be given. The subnitrate is best given in suspension in mucilage with a little spirit of chloroform or brandy: *e.g.*,—

℞ Bismuth. subnit., gr. x;
Mucil. acaciæ, ʒi;
Spts. vini Gall., gtt. iii to v.
Misce.
Sig.—One dose.

To be efficient it must be given in large doses,—*i.e.*, two to three drachms daily to a child a year old. It always blackens the stools. No remedy in these cases has held its place during the last ten years, it is safe to say, so firmly as has bismuth.

Iodoform may be given in powder in doses of from two to four grains every two hours to a child a year old. It has not been extensively used, and testimony as to its value is still conflicting.

Of drugs which may be expected to act upon the greater part of the small intestine there are two,—calomel and salol. This use of calomel is quite distinct from that as a cathartic already mentioned. This drug has the advantage of allaying vomiting as perhaps no other drugs of the antiseptic class do, and it seems to act best in cases where the stomach is specially involved. The most beneficial effects are generally obtained from it when it can be given during the first day of the illness. It is not of much use to continue it for more than two days at a time. The tablet triturates are the best form of administration, and from one-twelfth to one-sixth of a grain every hour to a child a year old the proper dose and the best interval.

Gray powder may be used in the same way in half-grain doses, with similar effect.

Salol, there is pretty good reason to believe, is decomposed in the intestine into carbolic and salicylic acids. It is of unquestioned value in these cases, although its first advocates, Goelet,[36] Osborne,[37] and others, have certainly overestimated its efficacy. It is best given in suspension in doses of two or three grains every two hours to an infant a year old.

Freely soluble antiseptics cannot be expected to do more than act on the stomach and the first part of the small intestine: their chief effect must be in the stomach. Whether it is necessary that these substances be given in quantities sufficient to control bacterial growth altogether, as shown by their behavior outside the body, or whether the inhibition to such growth which much smaller amounts produce is sufficient for practical purposes, we cannot yet say positively. Certain it is that there are few if any drugs which can be tolerated in the stomach in a quantity sufficient to disinfect a similar mass outside the body, when the organ is already disturbed by disease.

It appears probable that what is required practically is to retard the bacterial growth, and that this can be done by smaller amounts. The drugs of the class mentioned which experience so far seems to show to possess real value are benzoate of sodium, resorcin, creasote and carbolic acid, salicylic acid and its soluble salts (the salicylate of sodium seems to be decomposed into salicylic acid), and certain acids, especially hydrochloric and lactic.

Benzoate of sodium is used largely in Germany, where it is recommended by the best writers, but not to any great extent in this country. It can be given in doses of from half a grain to two grains. Larger doses are objectionable, according to Baginsky. The advantage claimed for it is that it is not likely to disturb the stomach.

Resorcin has been widely used in all parts of the world. While strongly antiseptic, its toxic properties should be remembered, and it must be used somewhat cautiously. It may be given in doses of from one-fourth of a grain to one grain, in solution.

Salicylate of sodium has been in my hands more satisfactory than any other of the drugs of this group. It is to be given in doses of two or three grains every two hours to a child a year old. It should always be largely diluted, preferably in the food. The calcium salt is preferred by some writers. To answer the objection raised in some quarters, that the salicylate of sodium is not an antiseptic and does not act as an antiseptic in the intestines, we quote the experiments of Vaughan,[13] who found that in the proportion of one to two hundred in milk it prevented the development of an active poison which had been added. Proper control experiments were conducted. It seems likely that all these salts act by being decomposed in the stomach, setting free salicylic acid.

The bichloride of mercury is still used by many, but in my hands it has been very unsatisfactory. Carbolic acid and creasote were much in vogue ten years ago, and they certainly possess real value.*

There is another point of view from which the use of antiseptics in the stomach and intestines is to be considered,—viz., the effect of these drugs upon digestion. Experiments made in artificial digestion outside the body cannot be taken as representing exactly conditions existing in the organs, particularly in disease. Furthermore, results from experiments so far made are somewhat conflicting, and hence not altogether to be depended upon. They show, thus far, that almost all the substances here included as antiseptics, with the notable exceptions of calomel and bismuth, have a considerable effect in retarding peptic digestion. This objection should not deter us from prescribing any drugs the use of which practical experience has shown to be valuable.

A careful review of this whole subject from both a theoretical and a practical stand-point brings us to the conclusion that asepsis is better than antisepsis; asepsis being taken to include thorough cleansing of the canal, and the administration of foods free from germs and so selected as to be as completely absorbed as possible, leaving but a small residue. To this must be added pure air.

Acids.—The use of acids in this class of diarrhœas has been advocated, for the following reasons:

(1) Moncorvo[35] has found a notable diminution in the amount of hydrochloric acid in the stomach.

(2) Lesage[9] took the reaction of the intestinal tract in fourteen autopsies made within forty minutes after death: the only parts constantly acid were the transverse colon and the descending colon. The small intestine was neutral. It is a well-known fact, confirmed by several observers, that the small intestine in healthy infants upon an exclusive milk diet is acid throughout.†

(3) Pfeiffer's[27] experiments appear to prove that the green stools which form so characteristic a feature of a large number of these cases are associated with alkalinity of some part of the intestinal tract. (See green stools, *ante*, p. 97.)

(4) Acids have been recommended as antiseptics on account of their well-known power in checking bacterial growth. The acids most widely used have been hydrochloric and lactic. The latter is advocated by the French writers to be given in half-teaspoonful doses of a two-per-cent. solution, administered every half-hour to every four hours according to the severity of the symptoms. It is recommended to be given about twenty minutes after feeding. I have never been able to give much more than one-fourth the doses recommended, and even then vomiting was often excited.

---

* For other antiseptics and their use in diarrhœa, see "Antiseptic Treatment of Summer Diarrhœa," by the writer, New York Medical Journal, January 29, 1887.

† Escherich,[15] p. 157.

My own experience leads me to prefer hydrochloric acid, of which from half a minim to five minims of the dilute acid may be given every two hours, well diluted. Neither of these acids should be given with milk unless the latter has been completely peptonized.

The relative value of acids we are not yet able to state, from the conflicting reports regarding them: on theoretical grounds they seem to be indicated, and practical experience has shown that in certain cases they are especially valuable. I have found them most useful in the subacute cases with undigested food in the stools, and particularly when combined with pepsin, but in acute cases they have been disappointing.

Alkalies.—Lime-water, magnesia, and chalk mixture serve a very useful purpose when there is acid fermentation of the stomach, but their effect upon the intestine is rather doubtful and uncertain.

Astringents.—The vegetable astringents containing tannin, such as kino, catechu, etc., were in former times largely used for this class of diarrhœas. My own experience accords with that of many recent writers in attributing to them little or no value; while the disturbance of the stomach they so often produce when given in large doses makes them in many cases positively injurious.

Of the mineral astringents, with the exception of bismuth, which has been referred to under the head of antiseptics, scarcely more can be said. They cannot be given in doses sufficient to produce any local effects without doing harm.

Opium.—While required in some form or quantity in almost every case, as it is frequently given opium does much more harm than good. In order to use it intelligently, and hence efficiently, it should be remembered just what the action of opium on the intestine is. Nothnagel[21] (p. 69) has shown, as a result of his carefully-conducted experiments, that its principal action is as a stimulant to the inhibitory nerves of the intestine, thus checking peristalsis; its action in diminishing secretion is regarded as a doubtful one; it seems to diminish the irritability of the sensory nerves.

The one symptom against which we are to use opium, then, is the increased peristalsis which accompanies almost every intestinal disorder and continues after the cause has been removed. It is possible by large doses of opium to stop peristalsis almost entirely; the effect of this in fermentative diarrhœas is to be compared to that of stopping the discharge from a large suppurating cavity while active decomposition is going on.

As a general rule, it may be laid down that opium is contra-indicated until the intestinal tract has been thoroughly emptied by cathartics or by irrigation. If the number of discharges is small, or if these are very offensive, it is not indicated. It is especially to be avoided when marked cerebral symptoms and high temperature coexist with scanty discharges. It is indicated early in the disease as soon as the canal has been thoroughly emptied of putrefying contents; also in certain cases, which are quite common, where the administration of food is immediately followed by a movement of the bowels; also where, without an elevation of temperature, and often with a good appetite, undigested food, especially fat, constantly appears in the stools, which are frequent, because the intestinal contents are hurried along so rapidly that there is not sufficient time for complete digestion and absorption.

Nothing requires a nicer discrimination than the use of opium in diarrhœa. In all cases I make it a rule to give it in a separate prescription and never in composite diarrhœal mixtures. In this way it can be increased, diminished, or stopped altogether according to the effect desired, while the other remedies used may be continued without interruption.

As to preparations, there is no great choice: paregoric, the deodorized tincture, and Dover's powder have been my preferences.

As to dosage, great variations are required in different cases; enough is to be given to produce a certain effect,—the diminution of pain and control of the excessive peristalsis,—but opium should never be used to the degree of locking up the bowels entirely, or of causing marked drowsiness or stupor. For an average child of one year, eight minims of paregoric, one-fifth of a minim of the deodorized tincture, or one-fifth of a grain of Dover's powder may be used as an initial dose, to be repeated every one, two, or four hours, the frequency being gauged according to the effect produced. Better results are generally obtained by the frequent use of smaller doses than from large ones at longer intervals.

If following the use of opium and a consequent diminution in the number of discharges there is no improvement in their character, and a rise of temperature occurs, too much has been given, and the amount must be greatly reduced or the drug stopped altogether.

Other drugs which have a certain amount of reputation in various quarters are arsenic and ipecac. From neither of these means have I been able to obtain any beneficial effects in acute cases.

Digestive Ferments.—Pepsin and pancreatin (extractum pancreatis) are valuable additions to our therapeutics. Predigested foods have already been spoken of under dietetics. These ferments may also be given in powder or scale form, the pepsin immediately after feeding, and pancreatin one hour after, with decided advantage. The preparations which I have found most satisfactory, because most active, are those of Fairchild Brothers and Parke, Davis & Co. A large number of those sold in the shops are absolutely inert. In the cases with gradual onset these ferments are of very great value. They are also useful during convalescence.

Stimulants are given with advantage in a very considerable proportion of the cases. The amount of prostration is often great and develops rapidly. It frequently happens that practically no food is assimilated for twenty-four or even forty-eight hours, while the drain of the diarrhœa continues. The general condition of the patient is the best guide to the time for stimulation and the amount to be given. Stimulants should be given more frequently and earlier than they usually are. Brandy is the best preparation for general use, champagne being perhaps preferred when there is very much vomiting. An infant a year old will take an ounce of brandy in twenty-four hours with advantage: sometimes double the quantity will be required.

General considerations in treatment:

1. All cases must be watched carefully and seen frequently.
2. The character of the discharges is in most cases a better indication than is their number of the condition of the patient and of the effect of remedies. Nothing is simpler than to give opium enough to reduce the number of passages, but unless there is some other sign of improvement one has probably done little good and may have done much harm.
3. We must treat the *patient,* and not direct all our thought to acid or alkaline stools, ptomaines or bacteria. Every therapeutic measure must contribute to one end,—viz., the improvement in the patient's general condition. The value of everything is to be estimated by its effect upon this.
4. No matter how strongly we may be convinced of the value of any drug or combination of drugs, if these continue to disturb the stomach they are worse than useless.
5. The use of all drugs is of very minor importance as compared with dietetic and hygienic treatment.
6. In the matter of antiseptics we shall be working in the dark until the life-history of the important intestinal bacteria is understood.
7. Great care is necessary in every case for two or three weeks after an attack, from the strong tendency of the disease to recur.
8. In the management of any single case, the important points are thorough evacuation of the stomach and bowels, then rest to these organs for from twelve to twenty-four hours. No cases do worse than those whose mothers cannot appreciate the value of starvation and who insist upon giving milk in violation of the rules laid down.

II. CHOLERA INFANTUM.

In comparison with the frequency of the foregoing class of cases those of cholera infantum are rare. They include in my experience not more than two or three per cent. of the cases of summer diarrhœa.

The term should be restricted to cases of genuine choleriform diarrhœa. Much confusion has arisen from adopting this term as a generic one for all cases of summer diarrhœa.

Etiology.—This variety is almost never met with in children who are entirely breast-fed. It is never seen except in warm weather. It occurs in very young infants not infrequently, but most of my own cases have been in those from six to fourteen months: age probably has no special influence except in relation to feeding. It is most frequently engrafted upon a mild dyspeptic diarrhœa.

The exciting cause is to be found in almost every case in the food which has been given.

Symptoms.—It occasionally happens that cholera infantum occurs suddenly in an infant previously healthy, but this is the rare exception. It is the rule that there is antecedent intestinal disorder: this may be in the nature of a mild dyspeptic diarrhœa of two or three days' or even weeks' duration, or the disease may supervene in the course of a subacute enterocolitis with such severity as to carry off the patient in a few hours.

The development of the choleriform symptoms in all cases is rapid, so that in the course of five or six hours a child who perhaps has been regarded as scarcely ill is apparently brought to death's door.

There may or may not be antecedent symptoms of a general character—prostration and a steadily rising temperature—for some hours before the vomiting and purging begin, or these may be the first things to excite attention and alarm. The vomiting may precede the diarrhœa, or both may begin about the same time. The vomiting is often incessant. First whatever food there is in the stomach is rejected, then serum and mucus, and finally bilious matters. If it subsides for a time it is almost sure to be excited anew by the taking of food or drink. The peculiarity of the stools is that they are frequent, large, and very watery. It often happens that in the course of half a day twelve or fifteen passages occur. When less frequent they are proportionally larger. They are of a pale-green, yellow, or brownish color in the earlier part, but as the stools become more and more frequent they often lose all color, and they are almost entirely serous. The sphincter is sometimes so relaxed that the evacuations occur every few minutes in smaller amounts.

The first stools are usually acid, later they are neutral, and the pure serous stools are usually alkaline.

In the majority of cases the stools are odorless: only in rare instances are the exceedingly offensive stools seen; at times the odor is overpowering. Microscopically the stools show large numbers of epithelial cells, some round cells, and immense numbers of bacteria.

Loss of weight is more rapid than in any other pathological condition in childhood. Baginsky records one case which lost three pounds in two days.

The fontanel is depressed, and in rare instances an overlapping of the bones of the skull may occur.

The general prostration is great almost from the outset. The children lose strength very rapidly. The face indicates better, perhaps, than any single symptom what a profound impression has been made upon the system. The eyes are sunken, the features drawn, the mouth depressed at its angles, and a peculiar pallor is spread over the whole countenance, with an expression of anxiety. In the early stages the nervous symptoms are those of irritation; children cry loudly or moan, throw themselves about in their cribs, are peevish, fretful, and quiet for but a few moments at a time. Sometimes they become almost wild in their excitement. Later these symptoms give place to heaviness, stupor, relaxation, and coma or convulsions.

The temperature, in my experience, has been almost invariably elevated, and usually in proportion to the severity of the case. The common elevation in recovering cases has been to 102° to 103° F., while in fatal cases it has risen almost at once to 104° or 105° F., and remained at or above that point till death, or it has risen steadily until shortly before death it has reached 106° or even 108° F. These rectal temperatures often occur with a clammy skin and cold extremities, and are discovered only by the thermometer. Nothing seems to modify essentially this high temperature. Many writers speak of subnormal temperature in the later stages, but such has not been my experience.

The pulse is always accelerated,—150 to 200 a minute. Very soon it becomes weak, often irregular, and finally almost imperceptible.

The respiration is irregular and frequent, and may be stertorous.

The tongue is generally slightly coated, but soon becomes dry and red, and is often protruded.

The abdomen is soft, elastic, rather retracted, and very compressible.

There is almost inextinguishable thirst. Everything in the shape of fluids, especially ice-water, is drunk with avidity, even although vomited almost as soon as it is swallowed.

There is very little urine passed, there may be none at all for twenty-four to thirty-six hours; yet this need give no great concern, with such frequent discharges from the bowels as exist.

Symptoms such as those described rarely continue two days without a decided change either for better or worse; in most cases it occurs in twenty-four hours. In the fatal cases there are the hyperpyrexia, the cold, clammy skin, the absence of radial pulse, stupor, coma and convulsions, and death. The diarrhœa and vomiting may continue until death, but more commonly the vomiting, and very frequently the diarrhœa also, cease altogether for some hours before death occurs.

In some cases the patients pass into a condition resembling the algid stage of epidemic cholera, with pinched, sunken features, subnormal temperature, dyspnœa, and cool breath, and death occurs in collapse.

In other cases, after the first stage of very severe symptoms has subsided, the discharges may diminish somewhat and the nervous symptoms become specially prominent. There are restlessness and irritability or apathy and stupor. The fontanel is sunken; the eyes are half open and covered with a mucous film; respiration is irregular and superficial, sometimes even Cheyne-Stokes; pulse feeble, irregular, or intermittent; extremities cool; muscles of neck drawn back; abdomen retracted; no desire for food, rousing only from thirst. The temperature in these cases is not elevated, but normal or below. From this condition recovery may take place, with gradual abatement in the nervous symptoms, improved pulse and peripheral circulation, and desire for food, the stools gradually becoming more consistent and having more color; or the symptoms may pass into those of entero-colitis, which may last indefinitely. Much more frequent than either of the foregoing is the fatal termination, either in convulsions or in coma from exhaustion or with a recurrence of the severe vomiting and purging.

These symptoms of diarrhœa have been grouped by the earlier writers, first by Marshall Hall, under the head of spurious hydrocephalus, or hydrencephaloid. They have been variously explained by different writers as due to cerebral anæmia, cerebral hyperæmia (venous), œdema of the meninges, thrombosis of the cerebral sinuses, and uræmia. Regarding the cerebral changes, I can only say that in but a single instance have I met with any which bore any proper relation to the symptoms.* Although I have examined the brain in almost all my autopsies in diarrhœal diseases, I have never seen in such cases thrombosis, and but rarely œdema. Cerebral hyperæmia was often met with in cases dying in convulsions, but not with any regularity otherwise. Nor have my observations upon the kidneys confirmed the observations of Kjellberg, whom most of the writers since his day have quoted, as to the great frequency of nephritis. Small quantities of albumen in the urine are not uncommon in these cases, but casts and renal epithelium are very rare, and blood I have never seen. The kidneys at autopsy are found generally paler than normal, with a moderate cloudy swelling of the cortex, but not more than is seen in many other febrile disorders of infancy, as, for example, pneumonia.

These facts forbid our regarding either the renal or the cerebral changes as an explanation of the nervous symptoms under consideration. It seems much more in accordance with our present ideas of pathology to consider them as chiefly toxic in character, due to the absorption of poisons developed in the intestines by bacteria there present.

In cases going on to recovery, severe symptoms rarely last more than twenty-four hours before signs of improvement are visible. The vomiting usually ceases first; the stools become less frequent, contain more solid matter, and have more color. There is coincident improvement in the pulse, the temperature falls, and nervous symptoms subside. This last is always to be looked on as a most favorable symptom. Sleep comes, and the great restlessness and irritation pass off. The discharges now partake more of the character of a catarrhal diarrhœa, which lasts a week or more. The great drain upon the system is slowly supplied by nutrition. Convalescence is never very rapid. Sometimes, after all signs of improvement have continued for two or three days, the choleraic discharges return with severity, and the case proves fatal.

Sclerema.—This is an infrequent sequel of cholera infantum, and has been described by several German writers, best by Widerhofer.[39] It is met with only in the most feeble children and in young infants, and is characterized by an induration of the skin and subcutaneous fat, so that these tissues become everywhere hard and board-like. The body is stiff, cold to the touch, and resembles a half-frozen cadaver. The condition is found associated with contractions, subnormal temperature, and other signs of the most complete prostration. These cases are almost invariably fatal. I have never seen sclerema, nor am I aware that it has ever been described in this country, as a sequel of cholera infantum.

---

* In this infant the cerebral symptoms were so marked and so characteristic that two excellent physicians who watched the case made the diagnosis unhesitatingly of meningitis. The intestinal symptoms were considered of secondary importance. The autopsy revealed follicular ulcers of the ileum, marked parenchymatous nephritis, and an extreme degree of cerebral anæmia.

Pathology.—What has been said already in the general section on bacteria applies with especial emphasis to cholera infantum. There is no form of diarrhœal disease met with in which the evidence is so strong of its bacterial origin. Its resemblance to Asiatic cholera is very close. The uniformity in its symptoms, the absence of pathological findings of an inflammatory character, and its close connection with the feeding of cow's milk are all well established.

In the absence of proof to be derived only from experimental bacteriology, positive statements are, of course, impossible. Still, we believe that such study will in the future show the dependence of the disease upon one or more forms of bacteria, and that the symptoms depend upon the absorption from the intestine of the ptomaines formed by such bacteria, either in the food before it is swallowed, or within the body.

The effects are grouped under three heads:

1. Toxic symptoms,—high temperature, prostration, and other nervous symptoms.

2. Paralysis of the vaso-motor nerves of the intestine, resulting in the enormous transudation of serum, which makes up the chief bulk of the stools.

3. Rapid wasting and excessive thirst from abstraction of fluids.

Diagnosis.—Cholera infantum can scarcely be mistaken for any other form of intestinal disease if its chief symptoms are kept in mind. The constant vomiting, the profuse serous stools, the great thirst, dry tongue, high temperature, and great restlessness, followed by rapidly-developing collapse, sunken fontanel, pinched, anxious face, cool extremities, weak pulse, dyspnœa, cyanosis, stupor, coma, convulsions, and death, all occurring in the course of one or two days, are unmistakable.

The only things with which the disease can be confused are acute gastro-enteritis and acute dyspeptic diarrhœa.

From the first it is distinguished by its shorter course, by the more intense nervous symptoms, and by the stools, which in cholera infantum are very thin, soon almost entirely watery, and colorless; in inflammatory diarrhœa they are green or greenish yellow, contain mucus, and are not so large nor so frequent.

In acute dyspeptic diarrhœa we have, as in cholera infantum, the sudden development of quite severe symptoms, with vomiting and diarrhœa, but both are less in degree; the temperature is not often so high, and it usually falls when the canal has been freely emptied; the stools contain undigested food, much gas, and are very foul, but we never have the pure serous stools; the prostration and all the nervous symptoms are very much less, and the disease very rarely proves fatal.

Prognosis.—The prognosis is worse in a young infant, worse in one who has been badly fed and poorly cared for, worse when all the surroundings are unfavorable, worse when the patient has suffered from antecedent intestinal disease, and worse in midsummer. Yet almost every year I see stout, well-nourished infants of ten or twelve months, who have been tolerably well cared for, die from this disease. There are certain cases in which it is evident, from the first few hours of their sickness, that death will be the issue. In such cases it is simply cruel for the physician to intimate to the parents that the result might have been different if he had been called in time. No matter what treatment is employed, and no matter how early it is begun, the vast majority of the very severe cases terminate fatally.

The prognosis, then, depends, more than on anything else, upon the severity of the attack.

The symptoms indicating a bad prognosis are hyperpyrexia, 106° to 108° F., profound nervous depression, and uncontrollable vomiting. Favorable symptoms in the course of an attack are cessation of the vomiting, a falling temperature (not subnormal), quiet sleep, and improvement in the pulse and cutaneous circulation. No case, no matter how severe, should ever be despaired of.

Treatment of Cholera Infantum.—The confusion in the use of the term cholera infantum is especially unfortunate when we consider the question of treatment: so many different things are included by writers under the term that it is difficult to estimate the results of various methods of treatment.

Restricting the term to the class of cases described above, all who see much of the disease must be in candor compelled to admit that the results of treatment are extremely unsatisfactory, and that the most severe cases pursue their course but little if at all influenced by the treatment employed. This statement is made after personal trial of almost every method of treatment which has been advocated by writers upon the subject.

In the way of prophylaxis much can be done. All the general rules of prevention laid down in the general section on that subject should be enforced here. Special emphasis, however, is to be laid upon the early treatment of the milder intestinal derangements, since it is a rule to which the exceptions are few, that such symptoms precede for some days the occurrence of the choleriform diarrhœa.

No cases of dyspeptic diarrhœa are to be neglected in summer on the score of an existing dentition; every case is to be attended to early and treated energetically, with the idea that at any time a sudden development of dangerous symptoms might occur.

The same remarks apply to convalescence after entero-colitis. Vigilance should not be relaxed for a day until the stools are normal, so often does one see cases which have been progressing, so far as it is possible to judge, steadily towards recovery cut off in a day by the development of cholera infantum. Unremitting care, and attention to all food, especially milk, must be kept up during the entire hot season.

The main indications to be met in cholera infantum are—

1. To arrest the discharges.
2. To strengthen the heart and sustain the system.
3. To reduce the temperature.
4. To allay nervous symptoms.

It is not desirable, were it even possible, to enumerate all the drugs and therapeutic measures which have been recommended.

The best view of treatment will be had if we keep in mind that these are essentially cases of poisoning, that the toxic materials act by causing great depression of the heart and the strength generally, by acting on the nerve-centres, and paralysis of the vaso-motor system of the intestinal vessels through the splanchnic nerves, and that we are not treating intestinal catarrh, nor intestinal inflammation, although intestinal inflammation is one of the results of the process which is likely to follow if the patient survive the first overwhelming shock of the poison. Nothing in my hands has proved so generally useful as the hypodermic use of morphine in combination with atropine. Although it is capable of doing great harm, I believe it is still of more value than any other means of treatment we possess.

The special symptoms indicating opium are very abundant vomiting and purging, nervous excitement, restlessness, delirium or convulsions, and feeble pulse. Opium is contra-indicated where the purging has ceased or is slight, and where there is drowsiness, stupor, or relaxation. The effects should always be carefully watched, and a small dose repeated is better than a single large dose. For a child a year old not more than one-hundredth of a grain of morphine and one-eight-hundredth of a grain of atropine should be used as the initial dose. It may be repeated in an hour unless the desired effects are produced. These are arrest of the vomiting and purging, or at least a great diminution of them, improved heart's action, and improvement in the nervous symptoms. Here, as in shock, we find morphine our most reliable heart-stimulant.

The use of opium by the mouth is not to be relied upon, owing to the uncertainty of absorption and the liability to produce vomiting.

Henoch [40] has reported favorable results from the free use hypodermically of a one-per-cent. saline solution.

In the treatment of the hyperpyrexia all drugs are useless. Even where they are retained, we get little or no effect from antipyrin, antifebrin, and drugs of this class, used in any safe doses. The only means to be relied upon is cool baths. The child should be put in a tub-bath at the temperature of 100° F., to avoid shock and fright, and the temperature of the bath gradually lowered by adding ice to 85° or 88° F. This may be kept up for from ten to thirty minutes, according to the amount of reduction in temperature effected. Baths to be efficient must be used at very short intervals, as often as every hour if symptoms are threatening. Iced cloths or an ice-cap should be kept applied to the head. Ice-water injections are a valuable accessory to the treatment by baths. A rectal tube should be used, and the injection carried high up into the colon, the water being allowed to flow in and out freely.

The only things to be allowed by the mouth are champagne and brandy and ice. They must be given in minute quantities every few minutes. Sometimes even these cause vomiting; then everything must be withheld and stimulants used hypodermically. Either brandy or ether may be employed; they should be used freely. To attempt to give food by the mouth, astringents, or in fact drugs of any kind, is worse than useless.

After vomiting has stopped and the purging is in a measure controlled, nourishment in very small quantities may be tried: for a young infant breast-milk should be obtained if possible. Cow's milk should not be employed unless completely peptonized. Whey, koumys, or kéfir may also be given, and they will usually be taken eagerly, on account of the thirst: beef or chicken broth may be tried in older children. The amount of food and the frequency of feeding must depend on the case. In the beginning everything should be tried in teaspoonful doses at half-hour intervals; later, if well borne, the amount may be cautiously increased and the intervals made longer. It is always to be remembered that during the most acute symptoms there is absolutely no digestion, and that it is some time after before the organs are able to dispose of much food. If the cases go on to a favorable result, subsequent feeding is to be carried on according to the principles laid down under the head of dyspeptic diarrhœa. After the stage of violent diarrhœa and vomiting has passed, if the symptoms described as hydrencephaloid are presented, the case is to be managed according to its symptoms. Opium is to be avoided; stimulants by the mouth are to be used freely where they can be retained, and, where not, hypodermically. If there are cold extremities and subnormal temperatures, hot mustard baths should be used to establish reaction, sinapisms applied freely all over the body, and hot-water bags or bottles used all about the patient. Baginsky recommends hot-water rectal injections. Camphor is sometimes useful as a stimulant.

Hygienic treatment during convalescence is all-important. If the patient survives the first violent stage, he should be removed as soon as possible: if in the city, to the sea-shore; if at the sea-side, to the mountains: a change of air is the important thing.

A continuance of the fever and diarrhœa without the extreme nervous symptoms and after the vomiting has subsided, means usually that the case has become one of entero-colitis: it is then to be managed like such cases beginning without the choleraic symptoms.

VIII. ACUTE ENTERO-COLITIS.

Synonymes.—Enteritis, Enteritis follicularis, Dysentery, Colitis, Ileo-colitis, Inflammatory diarrhœa.

The term ileo-colitis is perhaps preferable to the term entero-colitis, as being more exactly descriptive of this disease, or rather these diseases; but, as entero-colitis has become pretty generally accepted in literature, it is not advisable to displace it. The term follicular dysentery or follicular enteritis is open to very serious objection, for the reason that although inflammation of the lymph-nodules (solitary follicles) is the most common lesion, cases are seen, as yet indistinguishable from them clinically, in which the lesion is of quite a different character, these being either croupous or severe catarrhal.

The term acute entero-colitis is used here as a clinical one to embrace all the forms of acute diarrhœal disease with demonstrable inflammatory lesions.

For a description of these lesions the reader is referred to the general section on pathological anatomy. It need be remembered here only that the colon and the lower third of the ileum are the parts most affected, and usually the only parts affected.

Etiology.—Reference is again made to the general section on etiology. The factors of especial importance here are vitiated constitution and bad habits of feeding, especially in older children. Entero-colitis may occur at any time of year, although, of course, very much more common in the warm season.

Cold has long been regarded as a prominent factor, but with our present light upon this subject we cannot help thinking this view open to question.

This form of diarrhœa is occasionally seen as a complication of measles and scarlatina, but more commonly of diphtheria.

Symptoms.—Clinically three quite distinct forms are met with: first, the dysenteric form, which is primary; secondly, the more common acute variety, which usually begins as an acute dyspeptic diarrhœa or follows cholera infantum; thirdly, a subacute variety, which may follow either of the foregoing.

THE DYSENTERIC FORM.—These cases constitute but a small proportion of the class. They are more common in older infants than during the first eight months. The onset is sometimes quite abrupt, and sometimes gradual. In the abrupt cases we have often severe constitutional symptoms, the temperature rising to 104° or 105° F., prostration, not often vomiting, but severe nervous disturbance, frequently delirium, rarely convulsions. In the cases with gradual onset, which are much more common, the temperature is scarcely elevated at all, and the symptoms are almost entirely those of an intestinal character. After one or two fæcal stools, the discharges consist of almost pure mucus, or mucus streaked with blood, more rarely blood in clots. There is usually but little odor to these stools, but sometimes it is very marked. They are frequent, often every half-hour, and proportionally small, sometimes only a teaspoonful being found on the napkin after severe straining efforts. There are almost constant tenesmus and griping in severe cases. Prolapsus ani is a frequent complication, and sometimes a very troublesome one. As the case goes on, the passages contain more or less undigested food, and usually lose their peculiar character or have it only occasionally.

In severe cases there may be very great prostration, rapid wasting, and death, from exhaustion or from complications, in a week. More often they assume after a time the symptoms of an ordinary entero-colitis, and run a slow, indefinite course, with a tendency to frequent relapses.

These cases are described by many writers as cases of dysentery, a term of very uncertain significance, and, hence, objectionable. Used as it is by some to include all the varieties of inflammation of the colon, it is certainly a misnomer and has led to much confusion. As has been already stated in the introductory section, in the inflammatory diarrhœas of infancy and childhood it is the rule, to which exceptions are few, that the lesion is chiefly in the colon. Moreover, extensive lesions frequently exist without the symptoms commonly known as dysenteric. Dysenteric symptoms, such as have been described above, seem to depend upon the fact that the lesion is situated in these cases chiefly in the rectum and sometimes possibly in the sigmoid flexure.

There is no objection to the term when it is used to characterize certain symptoms only, and not to describe a pathological condition. We cannot now do better than to regard these cases simply as cases of colitis.

THE ACUTE FORM.—Much more common than the foregoing are the cases of entero-colitis which follow an acute dyspeptic diarrhœa or cholera infantum. When the latter, we have a cessation of the vomiting and the serous discharges, with a fall in the temperature, and many of the profound nervous symptoms pass off. The stools become more consistent, of a brown, gray, or greenish color, contain large quantities of mucus and undigested food, and are more or less offensive. Some appetite returns. The symptoms of shock which characterize the cholera-infantum stage pass away, and the pulse improves; but there are continued loss of flesh, some fever, usually 101° to 102° F., restlessness, peevishness, etc. These symptoms may last for two or three weeks, with exacerbations and remissions.

The exact relation of acute dyspeptic diarrhœa to entero-colitis is not quite clear. Clinically we meet with many cases characterized by the abrupt development of severe gastro-intestinal symptoms, vomiting, high temperature, diarrhœa, and nervous symptoms, which are convalescent in two or three days.

We see others in which there is improvement in all the severe general symptoms: the temperature falls nearly to normal, the vomiting ceases, and there is improvement in the nervous symptoms, but those belonging to the intestinal tract continue,—the stools being less numerous, less watery, less offensive usually, with less flatulence, but more mucus, and occasionally streaked with blood. Again we see cases in which there are two or three such initial attacks before the continuous diarrhœa is finally established, these being separated by a number of days, or even weeks, in which, as a rule, however, the stools never become quite normal.

There is another class of cases, not nearly so numerous as those just mentioned, in which the initial symptoms are indistinguishable from those described, but the severe inflammatory symptoms continue without any remission for from four to ten days, until death takes place, or, more rarely, they gradually subside after a variable time and the cases end finally in recovery.

It seems likely, then, that the majority of the cases of entero-colitis are preceded by an acute dyspeptic diarrhœa; that in some this is not set up until the second or third attack; and that in a smaller number a continuance of the severe initial symptoms makes it likely that there existed from the beginning an intense intestinal inflammation. In the last variety the autopsies confirm this opinion. Whatever the mode of beginning, when well developed the cases of entero-colitis present symptoms which are fairly constant and characteristic.

Temperature.—It may be stated as a rule to which there are few if any exceptions, that acute inflammatory lesions of the intestine are accompanied by fever, more or less continuous; and, conversely, that when we find a continuous temperature with intestinal symptoms we may safely infer inflammatory changes, the extent of which depends on the intensity and duration of the fever. This is an important point, for it often serves to differentiate entero-colitis from acute dyspeptic attacks. In the latter the temperature may be high, but is of short duration, since it does not depend on inflammation, but is rather toxic. There are no typical temperature-curves in acute entero-colitis. The temperature is usually higher in the beginning and towards the end of the disease. A high temperature towards the close is much more common than a subnormal temperature, although the latter is sometimes seen.

Hyperpyrexia in these cases is not common, but when it occurs it betokens usually an early fatal termination.

A rise in the temperature is often coincident with a great reduction in the number of the discharges, either from the use of opium or otherwise. Such temperatures are to be looked on as toxic, and demand purgatives, not antipyretics, for their treatment. It need hardly be said that complications at any time may cause a rise in temperature. The principal one to watch for is broncho-pneumonia.

Pulse and Circulation.—The pulse is always increased in frequency, generally in proportion to the other febrile symptoms. Frequency of pulse is of little or no diagnostic or prognostic significance. It is of great importance that the character of the pulse should be noted. In bad cases it is feeble, irregular, or intermittent. The capillary circulation is poor, and the extremities are often cold, even when the rectal temperature is elevated.

Nervous Symptoms.—These are marked in this as in almost all other intestinal disorders. In the early stage they are the symptoms of irritation,—great restlessness, constant crying from thirst or pain, rolling from side to side in the crib, biting at the fingers, scratching the face, etc. The later symptoms are of quite the opposite character, there being dulness, apathy, and general relaxation, so that these infants may lie sometimes for hours unless they are disturbed. These symptoms arise from a combination of causes,—partly from exhaustion and innutrition, partly from anæmia and loss of fluids, partly from fever, but chiefly, I think, they are toxic.

Mouth and Tongue.—During the early stage the tongue is usually coated heavily and moist; later it is often dry, red, and glazed; the lips crack and bleed readily. The buccal mucous membrane may be the seat of almost every variety of stomatitis; thrush is altogether the most common, and is seen most frequently in young infants. The condition of the tongue is of no diagnostic importance as a symptom of intestinal ulceration. Severe stomatitis of any form, and dry tongue and mucous membranes, are always unfavorable symptoms.

Vomiting is not a symptom depending upon entero-colitis. When present throughout the disease, which is exceptional, it depends upon coexisting gastritis. The great proportion of the cases have vomiting as an initial symptom, and here it depends rather upon the primary acute dyspeptic attack, in which the whole alimentary tract is more or less deranged.

Persistent vomiting developing in the course of entero-colitis is always a bad sign, and means often the supervention of cholera infantum and speedy dissolution. Single attacks of vomiting depend usually upon dietetic errors.

Stools.—The frequency varies greatly, and is usually inversely proportional to the size of the discharges. The small mucous passages streaked with blood may be from fifteen to thirty daily. Of the larger ones from four to ten daily constitute about the average. They are nearly always more frequent during the day than at night, which seems to show that the frequent feeding and handling of infants increase their number.

Diminution in the number of discharges is not always a sign of improvement; if this is accompanied by a rising temperature and increasing nervous symptoms, it is a bad sign. The stools sometimes cease entirely for from twelve to twenty-four hours before death, depending probably upon paralysis of the muscular coat of the bowel.

The reaction of these stools is usually acid, occasionally neutral, but in my experience very rarely alkaline.

The pure mucous stools are generally odorless; those containing much undigested food are frequently very offensive.

In color and consistency they vary almost without limit. They may be gray or grayish brown, bronze, yellowish green, grass-green, or yellow. They may be brown or black from blood, or from drugs, especially bismuth or iron. They are rarely watery except during exacerbations; they are semi-solid, but not homogeneous.

In composition they are an almost indescribable mixture of food-remains, intestinal secretions, blood, epithelial and pus cells, and bacteria.

The food-remains depend, of course, on the diet. If this is milk principally, white masses of fat are almost constant, with occasional curds. Various cereals—oatmeal, rice, barley, etc.—can be recognized by the naked eye, and all starchy foods by the iodine test or by the microscope. If only broths, peptones, and other predigested foods are given, the stool may consist almost entirely of intestinal secretions, mucus, bile, and epithelial elements.

Mucus is clear and glairy only when it comes from the lower colon. From the upper colon and the small intestine it is stained with bile and mixed with fæcal masses and undigested food. It is the most constant feature of these stools.

Blood is most frequently in small quantity, only enough to streak the stool faintly. Blood in clots or fluid blood is not common. It is an early symptom rather than a late one, and depends upon congestion and not on ulceration. In twenty of my own cases in which the autopsy showed intestinal ulceration, blood was entirely absent from the stools in fourteen.

Pus in quantity sufficient to be recognized by the naked eye I have never seen in children. In the severe cases pus-cells are found under the microscope quite uniformly.

Shreds of false membrane, or sloughs from the intestinal wall, I have rarely seen in the stools in infancy. They are not so uncommon in older children.

For the microscopical examination the reader is referred to the general section on diarrhœal stools. We cannot say that, as yet, this examination has shed much light upon diagnosis or therapeutics. For a discussion of bacteria see Dr. Booker's article in this volume.

The abdomen may be hard and distended during the early stage, while the dyspeptic symptoms are prominent, or at any time during the course of the disease when an acute exacerbation takes place. At other times it is natural, or retracted and soft. Tenderness on pressure along the line of the colon can sometimes be made out in older children. Enlargement of the mesenteric glands sufficient to be made out by palpation I have never seen in entero-colitis.

The appetite is in most cases impaired: it may be completely lost, and there may be disgust for almost every article of food. In some cases it is almost impossible to get the children to take anything in the shape of nourishment. Such a state of things greatly increases the difficulty of management and affects the prognosis very unfavorably.

The cases where children take willingly everything given are rare. They may do so from thirst when the temperature is high, but not at other times. It is more common for them to be apathetic and never ask for food or even for drink. A returning appetite and a relish for food are always very favorable signs.

The urine is nearly always diminished in quantity and high-colored, and frequently is loaded with urates. It is not uncommon to find a small amount of albumen, particularly when the temperature is high. But albumen in large amount, renal epithelium, and casts are exceedingly rare. I have met at autopsy with but a single case in which there was nephritis marked enough to have seriously diminished the patient's chances of recovery or to have formed an important factor in the fatal result.

Nutrition and Weight.—Failure of nutrition and loss of weight are more rapid in diarrhœal diseases than in any other disease of infancy. They depend on failure in digestion and absorption, and on the continued drain caused by the stools. An important factor is the increased peristalsis, which hurries the food along the intestines before absorption can take place. The loss of weight is not so rapid in entero-colitis as in cholera infantum, but it is steady and progressive, and is one of the best guides to the patient's nutrition. It is particularly important in the subacute cases and in convalescence to take the child's weight accurately and often,—at least twice a week,—as a guide to dietetic and medicinal treatment.

As emaciation goes on, the skin hangs loosely on the thighs and abdomen and can be pinched up in large folds. At the same time it becomes doughy, dry, and sometimes scaly.

Though rapidly lost, the flesh is slowly regained, and it may require many months to recover what is lost in two or three weeks.

Prolapsus ani is not a very frequent symptom, but is a very annoying one. It may occur only occasionally, or it may come with every stool. In the milder cases the tumor is the size of a small hen's egg and is flattened. In the severer ones it may be as large as a lemon. Reduction is in most cases easy, but retention is sometimes difficult.

SUBACUTE CASES.—After acute symptoms such as have been described have lasted for a variable time,—from two to four weeks,—the fever nearly or quite ceases, the stomach is quiet, food is readily taken, and most of the nervous symptoms have subsided, but the diarrhœa continues, and there is no improvement in nutrition: there is cachexia, with extreme anæmia. The stools in these cases are not very frequent,—only four or five daily; they continue to contain large amounts of mucus and undigested food, and are often of a very bad odor. They may improve for a day or two upon a change of diet or medical treatment, but soon return to the old condition. After such symptoms have lasted five or six weeks, there is gradual improvement in the stools and in weight, and the patient enters upon a slow convalescence, which is likely to be often interrupted by relapses, or the symptoms continue, and the case becomes one of chronic diarrhœa.

The different pathological varieties—catarrhal, croupous, and follicular—so much resemble one another clinically that it seems scarcely worth while to give each one a separate section. There are, however, points of difference which are fairly constant, and should be borne in mind.

The croupous variety, relatively rare, is the most intense of the three, and is characterized by the highest temperature and the severest constitutional symptoms. The temperature runs from 102° to 105° F.; blood in the stools is a frequent feature, and it sometimes comes in large amounts. The cases are frequently among those who were previously in good condition, sometimes in delicate subjects or those prone to diarrhœal attacks. The progress is steady and rapid, the symptoms lasting, in fatal cases, about a week. Cerebral symptoms are common, especially restlessness, irritation, and delirium. The appearance of shreds of membrane in the stools is about the only symptom which can be said to be positively diagnostic. But this is not often to be expected in infancy: the stools should be washed with water in looking for it.

Diagnosis being in a measure uncertain, it is impossible to say exactly what proportion of these cases recover, but it is certainly very small.

Acute Catarrhal Variety.—The very severe cases of this class resemble in all respects those of croupous inflammation. There are the rapid course, the intense symptoms, continuous high temperature, prostration, etc. The shortest case I have seen lasted three days. These cases are almost certainly fatal.

In the milder variety, much more common, the temperature is lower,—101° to 103° F.; the stomach is more apt to be involved, and the stools are more thin and watery. They are often streaked with blood in the early stage.

The great proportion of these cases recover. The acute inflammatory symptoms subsiding after a week or ten days, they are succeeded by mild intestinal derangement for from two to three weeks more; but the patients are often two months in regaining their previous condition of strength and weight. Relapses are common.

Follicular Ulceration.—The cases in which the lymph-nodules are principally involved are characterized generally by lower temperature, by less disturbance of the stomach, and by their slower and more irregular course. There is usually progressive emaciation. They last from ten days to eight weeks.

Desirable as it is, both for prognosis and for treatment, to know whether or not the lymph-nodules have broken down and formed ulcers in the intestine, it must be admitted that the diagnosis is still a matter of a good deal of uncertainty. The following is a *résumé* of twenty cases in which autopsy showed follicular ulcers.

Duration of disease:	Seven days or under (one five days)	2
	From twelve days to three weeks	12
	Four weeks and over	6
Previous condition:	Poor (one syphilitic)	11
	Good	6

It will be remembered in this connection that cases of tubercular ulceration are not included. It has been stated by Baginsky that the constant presence of pus-cells in great numbers in the stools may be regarded as pretty positive evidence of ulceration. My own experience in the microscopical examination of these stools has not been large, but so far it leads me to the view that, while the finding of pus as described is of considerable diagnostic importance, we are not to regard the negative symptom as having any special weight.

The diagnosis of follicular ulcers is rather to be made from the case taken as a whole. If a delicate infant which from time to time has been specially prone to diarrhœal attacks, especially if it has had symptoms of a mild catarrh of the colon, has an attack which starts in with green mucous stools and which continues with unabated severity for a week or ten days with low fever, we think of acute follicular inflammation as certain and of ulceration as probable. If these symptoms continue for three weeks without intermission, the child all the time failing steadily in strength, the probability becomes almost a certainty.

If, on the contrary, after three or four days of acute symptoms there is improvement in the stools, and one occasionally quite fæcal in character, and if after a few days another such exacerbation occurs, succeeded by another remission, and so on, we may be tolerably sure that no ulcers have yet formed.

If follicular ulcers have formed, the chances of recovery are small. The fact that these occur at all indicates usually a pretty active inflammatory process and little resistance on the part of the tissues.

The majority of the cases of "follicular" inflammation undoubtedly recover. In these cases there is probably only swelling of the lymph-nodules without ulceration, coupled with more or less catarrhal inflammation, the two being usually associated.

Termination.—Entero-colitis may terminate—

1. In complete recovery. Even in these cases there is usually a protracted convalescence of from three weeks to three months.

2. In recovery so far as the intestinal disease is concerned, but with such impairment of the constitution that the children fall an easy prey to pneumonia in the succeeding winter, or to any infectious disease which may be prevalent.

3. In death from exhaustion, with progressive failure in strength, and wasting. These cases last from three to six weeks, and include nearly one-half of the fatal cases.

4. In death after from four to ten days, with a continuance of severe inflammatory symptoms from the beginning.

5. In death from an exacerbation of acute symptoms in cases going on

apparently to a slow recovery. Such relapses and exacerbations are very easily excited.

6. In death from intercurrent cholera infantum.

7. In death from complications,—chiefly broncho-pneumonia and tuberculosis.

Complications.—*Skin.*—During the early acute stage an intense erythema frequently develops about the anus, nates, and genitals; in severe cases the thighs, loins, and legs are also involved. It is the result of irritation partly from the stools and partly from the frequent washing. The process may be superficial and result in a loss of epidermis only, or the corium may be involved and superficial ulcers form, and even sloughing may occur in bad cases.

An extensive erythema is a great annoyance and adds to the gravity of the case. Sloughing is rarely seen, and then only in patients who would almost certainly die from other causes.

Furuncles are very frequently seen during convalescence, and are particularly likely to appear upon the face and scalp.

Mouth.—Stomatitis is a very frequent complication of entero-colitis. The most common is the simple catarrhal form, which occurs both with and without dentition. In severe cases, especially when protracted, thrush is likely to develop. Occasionally, also, we meet with the small round follicular or aphthous ulcers. As a rule, the more the stomach is involved the more common are these buccal complications.

Glands.—Occasionally enlargement of the glands of the inguinal region is met with in the subacute cases, but this is rarely pronounced. I have never seen any degree of swelling of the mesenteric glands (unless tubercular) sufficient to be made out by abdominal palpation.

The other complications—broncho-pneumonia, tuberculosis, pleurisy, peritonitis, and nephritis—have been already discussed in the section on pathological anatomy.

Diagnosis.—The differential diagnosis of entero-colitis from cholera infantum and acute dyspeptic diarrhœa has already been discussed under these diseases. Entero-colitis is further to be distinguished from typhoid fever, tuberculosis, and intussusception. A doubt between typhoid fever and entero-colitis in infancy can scarcely exist. Notwithstanding the fact that from time to time cases of typhoid in infancy are reported, those under twenty months in which the diagnosis was confirmed by autopsy are extremely few. At this age it can be practically ignored.

In older children the difficulty is often a very real one. Typhoid is usually distinguished by its more constant fever, the enlargement of the spleen, the tympanitic distention of the abdomen, and most of all by the eruption. The fact of an epidemic prevailing is also to be considered.

The dysenteric form of colitis may be confounded with intussusception. If the possibility of this mistake is kept in mind it will not often be made. Yet the records of the cases of intussusception show that in the beginning a very large proportion of them had been regarded as cases of dysentery. In intussusception we have a very sudden onset (often the hour can be definitely stated by the mother); there are acute pain and tenesmus, followed by bloody and mucous passages. The amount of blood often is quite large,—as much as a tablespoonful of clear blood. There is vomiting, often persistent, with very marked prostration, but no fever. It is only at the outset that the mistake is likely to occur. The later symptoms—absolute stoppage of the bowels, an abdominal tumor, tympanites, rising temperature, collapse, and stercoraceous vomiting—have nothing in common with dysenteric colitis. In the latter there is rarely so abrupt a beginning or early vomiting; there is usually fever; the quantity of blood is generally smaller and the prostration is less.

The differential diagnosis from tuberculosis is considered under the head of chronic diarrhœa.

Prognosis.—In making a prognosis in a given case one must consider the child's constitution, its surroundings, the ability of the parent to carry out a proper line of treatment, the duration of symptoms at the time the case comes under treatment, the part of the summer in which the attack occurs, the existence of complications, and certain particular symptoms.

The prognosis is worse in a feeble or cachectic child, in one suffering from rickets or with inherited tubercular tendencies. It is worse in cities, among the poorer classes, and in institutions. The chances of recovery are much reduced if it is impossible for fresh air or change of air to be secured, and under all circumstances where the matter of diet especially cannot be looked after by an experienced nurse. The longer the symptoms have lasted, particularly febrile symptoms, the greater is the probability of severe anatomical changes and the worse the prognosis. Cases occurring in June or early in July have a worse prognosis than those occurring in the latter part of August or in September, for the reason that the earlier cases have still the greater part of the summer to get through and are likely to suffer from relapses during the rest of the warm season.

The prognosis is rendered less favorable by the existence of any complications, such as severe stomatitis, eczema, nephritis, and especially broncho-pneumonia and tuberculosis.

It is worse in children who have been previously badly fed, in those who have been recently weaned, and especially in those who have suffered earlier in the season from diarrhœal attacks. The particular symptoms which make the prognosis bad are a continued elevation of the temperature, frequent vomiting, rapid wasting, and continuous severe nervous symptoms.

It is never safe to give an absolutely good prognosis until the end of the hot season, on account of the great liability of these cases to relapses and recurrent attacks.

Treatment.—Prophylaxis involves all that has been said in the general section, with especial emphasis laid upon the necessity of early and prompt treatment of all the milder forms of diarrhœa, before the process shall have gone on to the formation of serious anatomical changes. Especial care should be taken to prevent over-exertion in children of two or three years in very hot weather.

Hygienic Treatment.—Almost all that has been said upon this point under Dyspeptic Diarrhœa is applicable here. Change of air from the city is imperative. If children are to be kept long away, inland is generally preferable to the sea-shore. The district should be high and dry and one in which the local surroundings are good. Even after they have recovered it is not safe to allow children to return to the city until the last of September, since a return during the warm season would be very likely to cause a second attack. If there has not been complete recovery, relapses follow almost inevitably.

Fresh air, pure air, and plenty of it, is a necessity for all cases. The same directions for bathing should be followed as are given under Acute Dyspeptic Diarrhœa.

It is still a debatable point whether children sent from the cities to suburban or sea-side hospitals do better in tents or in wooden buildings. My own experience is against the use of tents, as being hotter during the day, and so much cooler at night, especially during August and at the sea-shore, that there is greater danger of pulmonary complications. Great care must always be taken to see that children are warmly covered at night. This is often overlooked, as the days are so hot.

Dietetic Treatment.—In the early stage, if the stomach is affected the case is to be managed as one of acute dyspeptic diarrhœa. The gastric symptoms will usually have subsided at the end of two days, and we have then only the intestinal ones to deal with.

If an infant is nursing, and the breast-milk is above suspicion, there is no reason for its withdrawal.

If the infant is but a few months old, and hand-fed from the beginning, or just weaned, its life may depend upon securing a wet-nurse. Whenever this is possible it should be done, if only for a few weeks. If it is out of the question, we begin with barley-, rice-, or arrowroot-water, or thin mutton or chicken broth, and come back gradually to cow's milk. Milk may be tried as in dyspeptic diarrhœa, first completely peptonized (two hours), then diluted with four or five times its bulk of gruel made from "flour ball," barley flour, or rice (see page 116). If curds or fat-masses appear at once in the stools on the addition of the milk, it must be stopped and the white-of-egg mixture substituted. Or some of the prepared foods—Liebig's, Horlick's, or Mellin's—may be tried, made without milk. Condensed milk will sometimes agree when milk in other forms fails, but much oftener it will not.

The greatest care should be taken to see that the milk is the best that can be obtained, and that it is sterilized, or at least boiled, and kept on ice, never in the room nor out of the window. Milk which turns the blue litmus paper quickly should not be used; but this test is not enough, as much milk may be unfit for use from other conditions not revealed by litmus paper. Other useful articles are the meat extracts, which are generally inferior to freshly-prepared beef juice.

Raw scraped or pounded beef which has been put through a sieve and rolled into little balls with salt or sugar is sometimes a valuable resource. The danger of tape-worm has, I think, been greatly exaggerated. Two or three teaspoonfuls of this meat can be given daily.

These cases are apt to be protracted, and children soon tire of every food given; of milk least, so that whenever it can be borne we rely on it as our main-stay: if it appears in the stools undigested we must give it in greater dilution or stop it altogether.

The dangers of overfeeding and too frequent feeding are great. But the opposite one, of too little nourishment, should be avoided. These infants are often so dull and apathetic that they scarcely make a sign for food if it is withheld almost altogether. An exact record should always be kept of just how much the child does take, and the physician may find that a child of six months, who ought to get in bulk from twenty-four to thirty ounces in twenty-four hours, gets only eight or ten. Children should be fed regularly, not oftener than every two hours.

It is always important that foods giving as little residue as possible be chosen, so as to leave as little as possible to cause irritation and decomposition in the lower intestine.

In older children, the milk diet, or diet of milk and gruel of wheat or barley flour, alternating with mutton broth, usually succeeds best.

Especial care should be given to the diet during convalescence. Relapses come on very readily from all causes, but from nothing else so readily as from improper feeding. Especially to be avoided in younger children are oatmeal, potatoes, tomatoes, and, in fact, all vegetables and also all fruits. I have seen a single peach excite a dangerous relapse, and a few raisins a fatal one. The general rules laid down in the feeding of cases of dyspeptic diarrhœa might be repeated here with emphasis.

Medicinal Treatment.—In the early stages the case is to be managed as one of acute dyspeptic diarrhœa, by evacuants, antiseptics, and the judicious use of opium.

If, however, acute febrile symptoms have continued beyond the third day, we may be pretty sure that we have lesions of some consequence to deal with. It is to these, rather than to the putrefactive processes, that the subsequent treatment must in the main be directed.

It is of the first importance now that nothing should be done to disturb the stomach or the powers of digestion, which are always impaired to a greater or less degree. Hence we should be very cautious about overdosing our patients or giving any nauseating mixtures.

From time to time, according to indications, we may seek to aid stomach-digestion by the use of pepsin, hydrochloric acid, pancreatin, and alkalies, either lime-water or magnesia, added to the food. The progress of the lesions below depends very much upon how well we can nurse the feeble powers of digestion and absorption.

We do not hope by any of the above measures to influence the condition in the intestines directly, but indirectly.

Antiseptics are now of much less value than in the cases of acute dyspeptic diarrhœa. Calomel does but little good except in the acute exacerbations which come on from time to time, and resorcin seems in some cases to do harm. The salts of salicylic acid, both the sodium and calcium salts, and salol, given as previously directed, seem to do more good than anything else except bismuth. Whether the action of bismuth in these cases is astringent or antiseptic, or whether it acts mechanically by coating the inflamed surfaces, we do not know; probably it partakes of all three qualities. Bismuth frequently fails becauses the doses given are entirely inadequate. Doses of five grains of the subnitrate four or five times a day are almost worthless. At least two drachms a day should be given to a child a year old, and the amount increased proportionally for older children. If a good preparation is given, there need be no fears of unpleasant symptoms. I have never seen any from that manufactured by Squibb.

Talcum (silicate of magnesium) was long ago used by Trousseau with success, and its use has been recently revived by Debove and Sevestre.[41] It is a bland, inert powder, and is given in suspension in the doses in which we prescribe bismuth.

The commonly employed vegetable astringents, kino, catechu, krameria, etc., as well as the mineral astringents, acetate of lead and nitrate of silver, have been in my hands absolutely worthless, and the sooner they are dropped from our therapeutics in this class of diseases the better, I think, will be our results. Their only action is local, and, introduced in any sufficient dose to produce local effects, they almost inevitably disturb the stomach. Their local effect can be much better obtained by their use in enemata, under which head they will be referred to.

Opium is valuable in these cases, but must be used with great discretion. It is particularly indicated when the stools are thin, frequent, of a not very offensive character, and when they are excited by the ingestion of food. It is to be used with great caution when the stools are small, infrequent, and very foul, and also when there are marked nervous symptoms. It is always best given in a separate prescription and used occasionally for a specific effect. For doses and preparations reference is made to the remarks on the use of opium in acute dyspeptic diarrhœa. In the cases with dysenteric stools I have seen great benefit in many instances from the use of the old-fashioned emulsion of castor oil. A good formula is the following:

℞ Olei ricini,
Spts. vini Gall., āā ♏viii;
Mucil. acaciæ,
Aq. dest., āā ℥ss.
Misce.

Sig.—One dose for a child of twelve to eighteen months; repeat every two to four hours.

Opium is generally needed in these cases, but it is better to give it separately.

In these cases, and in some others where there is much colicky pain and tenderness of the abdomen, with stools streaked with blood, much benefit may be derived from a thin flaxseed poultice applied to the abdomen, or from mild counter-irritation by turpentine stupes or by mustard.

Stimulants are needed in almost all cases. There are no valid objections to their use even in young infants. If alcohol is ever justifiable in medicine, it is in these cases of intestinal inflammation, where we have extreme prostration, feeble powers of digestion and assimilation, and often a great repugnance to food of every kind. There is in these cases no more danger of acquiring the alcoholic habit than there is of acquiring the opium habit.

Stimulants are needed in the early stage as soon as the pulse becomes weak and the capillary circulation poor. At this time old brandy is the best preparation for most cases. Blackberry brandy is preferred by many. It should be given well diluted. As much as thirty drops every hour can be given to an infant of a year; in severe cases and for short periods, a much larger amount proportionally. It should be given for an effect, which is mainly an improvement in the pulse and in the patient's strength. In cases of sudden collapse it may with advantage be used hypodermically.

Other heart-stimulants are in these cases much inferior to alcohol.

In the subacute cases drugs do not seem of very much value. They are vastly inferior to hygienic and dietetic measures. Bismuth may be used for a considerable period, and seems to do more good than anything else. Opium is to be given only occasionally, as symptoms may require.

The prevailing tendency in practice is to overdose these cases. Often, after changing the treatment every fifth or sixth day for as many weeks, I have stopped everything except food and stimulants, and more than once have found patients to do better without drugs than with them. In these subacute and chronic cases it is advisable every week or ten days to stop all medication for two or three days, and see how the patient is. Overdosing very frequently does harm by its effect upon the stomach.

Local treatment is of very great value in these forms of diarrhœa. It will be seen by reference to the pathological anatomy that the lesion is chiefly in the colon, very often exclusively here, and that it is usually the lower half of the colon which is most seriously involved. Manifestly, then, if we wish to treat the lesions by drugs designed only for local effects, the proper mode of administration is by the rectum and not by the mouth.

Rectal injections are of two kinds: first, irrigation, which contemplates flushing the entire colon as far as the ileo-cæcal valve, large quantities of the fluid being used, it being allowed to flow in and out freely; secondly, the use of enemata or clysters, in which a smaller amount of fluid is injected and retained for some time in the intestine, for its local effect.

The method of irrigating the colon has already been described. (See

Dyspeptic Diarrhœa.) Its purpose is mainly to empty the intestine completely of all masses it may contain. It need not be repeated more than twice daily, and usually once a day is enough. As an injecting fluid a simple saline solution is generally preferred (one drachm of common salt to a pint of water): this is less irritating than plain water. If there is much mucus, a borax solution of the same strength may be employed. The water should flow in and out until it is quite clear, from one to two gallons being used at once. If the fluid has been properly introduced, the outline of the distended colon can usually be seen and felt. For general use a temperature of about 80° F. is preferred. In cases of collapse hot injections (110° to 115° F.) have been advised, and in cases of high temperature and active inflammatory symptoms ice-water may be used with advantage.

The use of antiseptic solutions—sublimate, carbolic acid, etc.—is not to be advised, from the danger of retention and absorption.

Enemata for local effect are generally used in quantities of from two to six ounces, according to the age of the patient. The intestine should first be emptied by an ordinary saline irrigation, except when nitrate of silver is to be used, when simple water should be employed. The clyster is used about half an hour afterwards, slowly introduced, the buttocks being pressed firmly together to prevent escape of the injection. A compress should be held against the anus by a nurse for from twenty to forty minutes, according to the nature of the enema and the effect aimed at. For use in this manner the following substances are to be preferred:

1. Bismuth suspended in mucilage (ʒss to ℥i), from four to six ounces being injected, and retained as long as possible.

2. Tannic acid dissolved in water (gr. xx to ℥i), used in the same quantity and in the same way as the bismuth solution.

3. Nitrate of silver (gr. ii to ℥i): inject four ounces, and in five minutes follow with a copious saline injection.

To all of these tincture of opium should be added, the amount being about twice what a full dose by the mouth would be for the child's age.

Of these the first two are to be preferred. The silver injections stain linen so readily that they are not pleasant to give; and when used in considerable quantity harm may be done unless they are carefully made and followed by the saline. The bismuth and tannic-acid solutions may sometimes be used with advantage in quantities considerably larger than those indicated above.

4. Bland mucilaginous mixtures, such as starch, salep, etc., usually with an opium addition.

In general, intestinal irrigation is more useful than enemata. It is valuable in all varieties and in all stages. It may be combined with enemata. Small injections of four or six ounces fill the rectum and sigmoid flexure, but not much more. They are most valuable, then, when these parts are the chief seat of disease, as in the so-called dysenteric stools. In these cases they are of very great value, as are also small injections of ice-water. For tenesmus when not relieved by these measures, suppositories containing half a grain of cocaine may be used, and sometimes act like magic. In subacute cases where the stools are not of the dysenteric type, we may safely assume that nearly the whole colon is involved, and our choice here is between simple irrigations and high injections of bismuth or tannic-acid solutions. Their use may be continued for several weeks with advantage, the character of the injection being changed from time to time.

During convalescence it is better generally to stop all treatment with reference to the bowels and to direct our efforts in the line of general tonic measures. The most useful tonics are arsenic, of which one or two drops of Fowler's solution may be given thrice daily for several weeks; iron, one of the best preparations for infants being the albuminate;* nux vomica, which may be combined with either of the above; wine, either old port or sherry; this may be combined with a bitter if there is thought to be danger of forming a habit; mineral acids, especially the nitro-hydrochloric, two to five drops of the dilute acid being given after meals, largely diluted in water. Cod-liver oil had best be deferred until the stomach and appetite are quite in order, but it is well to continue it through the succeeding winter months.

IX. CHRONIC DIARRHŒA.

Two forms of intestinal disease having chronic diarrhœa as a prominent symptom are excluded from the present section, because they are treated of in another part of this work,—viz., diarrhœa depending upon intestinal tuberculosis, and membranous enteritis or mucous disease. The remaining cases may be conveniently divided into two classes:

(1) *The primary cases,* in which there is often only a continued derangement of function, which after a time may induce anatomical changes (these changes may be absent; they are usually slight); the two principal etiological factors being depraved constitution and continued bad feeding. These cases commonly terminate in recovery when the cause can be removed.

(2) *The secondary cases,* in which the chronic disease follows an acute attack of entero-colitis, and in which there are usually very marked anatomical changes upon which the diarrhœa depends. The great proportion of these cases ultimately prove fatal.

THE PRIMARY CASES.

Etiology.—This form of diarrhœa is exceedingly common in children who are the subjects of rickets, syphilis, general tuberculosis (even when not involving the intestines), chronic broncho-pneumonia, and, in fact, any chronic cachexia. It is seen very much more frequently in institutions than in private practice. It may occur at any season.

---

* Prepared by Fraser & Co., New York. The dose is from ten to thirty drops for an infant.

It is very much more common in artificially-fed infants, yet it is not rare in those who are nourished at the breast exclusively. Among the latter it is seen sometimes in the early months, where it may be due to the composition of the milk, to the presence of colostrum, or to the excess of albuminoids and salts and deficiency in fat and sugar. This is seen among very young mothers, and those who, though delicate and anæmic themselves, yet feel it to be their duty to nurse their children. They often succeed in keeping up a large flow of milk by drinking largely of all fluids, and especially of malted drinks. It may occur also from prolonged lactation, where this is kept up until eighteen or twenty months because the mother fears to feed the child during its "second summer;" and, finally, it may depend on the mother's becoming pregnant.

In artificially-fed infants it may depend upon the nature of the food, or upon the manner of feeding, especially upon too frequent feeding or upon overfeeding. (See general section on etiology.)

It sometimes occurs as a sequel of some of the eruptive fevers, as measles or scarlatina. It may complicate pertussis, especially in summer. Insufficient clothing, especially of the extremities and the abdomen, is undoubtedly sometimes an exciting cause in infants who are constitutionally predisposed to chronic diarrhœa.

One attack always predisposes to a second. In older children the principal causes, as in infancy, relate to constitutional condition and to habits of feeding. It is not uncommon among children of the better classes who are allowed to select their own articles of diet from the table, and who choose habitually indigestible articles, sweets, highly-seasoned foods, tea and coffee, salads, patties, nuts, preserves, and cake, instead of plainer and more wholesome articles. These habits are the more likely to give serious trouble if the children are delicate city-bred children, as, indeed, they usually are. Worms in the intestines, particularly ascarides, may be the cause of chronic diarrhœa.

Symptoms.—*In Infancy.*—In the early part of the disease there are often the symptoms only of dyspepsia, without any actual diarrhœa. The passages do not exceed three or four a day; they are semi-solid, often pale, putty-like, and have usually an offensive odor. They contain large quantities of undigested food; if white or gray this is largely fat, and the foul odor is due probably to the formation of fatty acids. There is usually some flatulence and colic, often tenesmus, and the stools if hard and dry may be streaked with blood. After a while mucus appears in considerable quantity and becomes a marked feature of the stools. The color varies from gray or brown to green or greenish yellow: these green mucous stools have usually less odor than the gray ones. Such stools may continue for two, three, or even six weeks before the mother or nurse is sufficiently disturbed to seek advice. This is often sought only because the child's general condition has begun to suffer, and the pallor, the anæmia, the flabbiness of the tissues, and the loss of weight have attracted attention. Even now, as Eustace Smith[43] very justly remarks, if questioned regarding the bowels the mother is apt to insist that they are regular or that they are "nicely open," and that there is no diarrhœa. The condition may be habitual almost from birth, or the change may come on so gradually that the mother often reaches the conclusion that these stools mean nothing in this particular case, especially if the infant happens to be teething. It becomes a physician's imperative duty to inspect personally the stools of every infant who is not thriving, no matter what statements are made regarding the character of the discharges.

It sometimes happens that the constitutional condition remains good, the child gaining steadily in weight, in spite of the fact that its movements are always greenish yellow or green and contain mucus and undigested food. I have known of one such case lasting for five months, the stools gradually becoming normal at the end of that time without treatment. This infant was nursed entirely by a remarkably healthy mother, and it is quite likely that overfeeding was the principal causative factor. Such cases are exceptional. In the vast majority of children—always, I think, in those artificially fed—we have after a few weeks pretty marked evidences that the general constitution is being seriously undermined. The appetite is frequently unimpaired.

As the case progresses the stools generally become more frequent and thinner, and they may vary almost endlessly in appearance, this depending largely upon the diet. They are often of a dirty brown, watery character, sometimes consistent and resembling chopped spinach, usually offensive, and always containing undigested food. The progress is never steady in cases of chronic diarrhœa. Every week or two, depending upon the state of the weather perhaps, or more commonly upon the food, there are acute exacerbations for a day or two, which, if severe, are sometimes accompanied with vomiting and fever.

The diarrhœa may continue until a state of extreme emaciation and cachexia is reached such as is seen in the secondary cases, and death may occur from exhaustion. Very few of them prove fatal *per se;* it is much more common for them to die from the supervention of some of the acute forms of diarrhœa. In summer this is almost the universal termination of the fatal cases. If a child is exhausted and wasted from a long-continued chronic diarrhœa it does not take a very severe acute diarrhœa to carry it off. In winter these cases die from other complications, usually bronchopneumonia.

In the cases going on to recovery, there is noticed first a diminution in the nervous symptoms, fretfulness, irritability, and restlessness at night. Then we see an improvement in the stools. They become more uniformly consistent and contain less mucus, although the offensive odor may last a much longer time; and finally the infants begin to gain in weight. This gain is very slight at first, and may amount to only a few ounces each week. Convalescence is always protracted, and likely to be interrupted by relapses.

In older children chronic diarrhœa is seldom fatal unless dependent upon intestinal tuberculosis. But the cases are always obstinate, and peculiarly trying to the physician because of the great difficulty in removing the cause, which is generally pernicious habits of feeding.

There is here loss of flesh, not so rapid as that seen in infancy, and not usually so extreme ; there are irritability of temper, restlessness at night, and a capricious appetite, especially a craving for sweets or highly-seasoned food. The children become pale and anæmic, droop perceptibly, and tire readily on exertion.

The stools are not very numerous, in the beginning only three or four a day. They are at first pale, sometimes clay-colored, and nearly always very offensive. They gradually become thinner, and contain mucus as a constant feature. They are now gray, brown, or green mixed with yellow, and always contain undigested food, sometimes but little changed. Eustace Smith points out a peculiarity of these cases,—that the stools are excited by the taking of food, which is hurried along the intestine with great rapidity before there is time for digestion or absorption.

The course of these cases is indefinite : they may last for months or even years, getting now better and now worse, with the diet, the season, and the surroundings. After they are once well, they relapse from very slight causes, and throughout childhood they may never lose their peculiar susceptibility to diarrhœal attacks.

The general symptoms—loss of flesh and strength, and anæmia—are often seemingly out of proportion to the intestinal symptoms, so that some grave constitutional disorder is suspected, especially tuberculosis.

The foundation for rickets and for general or local tuberculosis is often laid by these attacks.

THE SECONDARY CASES.

Chronic diarrhœa may be preceded either by an attack of acute dyspeptic diarrhœa or by acute entero-colitis. If the former, it does not differ in its symptoms, course, or results from the cases which are primary and which have been just described. If the latter, it is much more serious.

These cases are usually seen in the fall months, and they comprise those which have barely managed to get through the summer months alive. No definite line can be drawn between the acute and the chronic stages. I shall include under the head of chronic cases all those which have lasted over six weeks, although some become chronic in a shorter time, and occasionally we see an acute case lasting longer.

In these cases the continuance of the diarrhœal symptoms depends upon the existence of intestinal lesions.

The symptoms of active inflammation have passed away ; the temperature is usually normal ; there is no pain or tenderness ; and food is taken readily, often with avidity. But there is no improvement in the general condition, and either the weight remains stationary or the child loses steadily until it is little more than skin and bones.

General Appearance.—The face is pinched, the features sharp, the eyes sunken, and the cheeks hollow. The lips are pale, often fissured, and bleed readily. The fontanel is depressed. The body is so small that the head seems much too large. Almost every vestige of fat may disappear from the subcutaneous cellular tissue of the trunk and extremities. The skin hangs in loose folds on the thighs. The abdomen is sometimes distended and tympanitic, and sometimes retracted and soft. The limbs seem like drumsticks.

Mouth and Tongue.—The mucous membrane of the mouth may be the seat of thrush, of simple catarrhal stomatitis, or of the follicular form, rarely of the ulcerative variety. The tongue is sometimes coated heavily, but is more often dry, glazed, and red. In rare instances sordes may cover the lips and teeth.

The teeth sometimes decay quite rapidly, from the general malnutrition. Baginsky states that the progress of dentition is arrested; but I have very often seen these infants—almost living skeletons—go on cutting tooth after tooth quite as steadily as under normal conditions, and Eustace Smith has made the same observation.

Appetite.—These children will, as a rule, take almost anything given them, and an almost unlimited amount. Yet, although they retain it, the more they are fed the more rapid sometimes seems the wasting. They rarely cry for food, however.

Vomiting is an uncommon symptom, and seldom occurs except from overloading the stomach, or from an acute exacerbation.

The *stools* are not frequent: five or six a day is about the average. Often they will drop to two or three a day for a week at a time. They are usually thinner than normal, but are not often watery. They invariably contain mucus, generally mixed with the other constituents and stained by bile. Blood is rarely present. The stools are sometimes green, often greenish brown, sometimes a pale gray. Undigested food is always present in quantity, and upon the diet depends very much the gross appearance of the stool. If milk is given, masses of fat and lumps of casein almost immediately appear in the passages. Vegetables come through often but little changed; so do the starches and cereals, and sometimes meat if this is given.

The odor of the stools is almost always offensive, sometimes extremely so. Nothnagel and Baginsky have called attention to one form of stools which they believe to be characteristic of wide-spread inflammation of the mucous membrane with atrophy of the tubular glands. These stools are of an almost normal consistence, homogeneous, in color like meconium, usually offensive, and sometimes alternating with those of a watery character. Under the microscope there are nuclei, but no unchanged epithelial cells. The food-remains are sometimes unrecognizable, from the extent to which decomposition has taken place.

Pus is nearly always to be found under the microscope, but is rarely visible to the naked eye.

Prolapsus ani is occasionally seen in these cases, though not so often as among the acute ones: when it does occur, however, it is generally more difficult to control, from the want of tone existing in all the tissues.

Flatulence and colic are marked symptoms in some cases, but absent altogether in many others. As a rule, there is neither abdominal pain nor tenderness. When the abdomen is enlarged it is most frequently uniformly so, but sometimes shows marked epigastric prominence, though from dilatation of the transverse colon rather than of the stomach. The skin of the abdomen often seems very thin; dilatation of the superficial veins is rarely met with. The liver and spleen are generally normal in size, so far as can be made out by physical exploration. Although the mesenteric glands are always enlarged, yet they cannot be felt through the abdomen. Enlargement of the inguinal and other groups of lymph-glands is mentioned by most writers as a symptom, but I have rarely seen any noteworthy swelling.

The *skin* is loose and wrinkled, dry and scaly, in the worst cases frequently covered with small petechiæ on the abdomen and lower extremities. About the anus, and over the sacrum, the thighs, the genitals, and sometimes the feet, there is very commonly erythema, from the continued irritation, and not infrequently ulcerations are seen.

The *pulse* is weak and rapid, the peripheral circulation is poor, and the extremities are cold much of the time unless artificial heat is applied. The respiration is usually shallow, and often irregular without any apparent cause. It becomes rapid from the development of broncho-pneumonia, bronchitis, or marked hypostatic congestion.

The *temperature* is not elevated, except during exacerbations, or from the development of inflammatory complications. A subnormal temperature is occasionally met with, but is not very common. I have occasionally seen it 95° F. in the rectum, but rarely lower. A continuous subnormal temperature usually means death in a day or two.

The *urine* shows no constant changes. It varies in quantity according to the fluidity of the stools and to the amount of liquid taken. Dropsy in the feet may be present in the late stages without albuminuria.

The *nutrition and weight* are stationary, or steadily fall to an almost incredible degree. I have seen one infant weighing at thirteen months eight pounds; another at two years and four months, thirteen pounds. There are marked cachexia and extreme anæmia.

Nervous symptoms are always present, and sometimes are of a very puzzling character. The children are usually cross and irritable, sleep badly, and frequently have a low whining cry which is kept up much of the time. Sometimes they are dull, apathetic, and quite indifferent to their surroundings. Persistent opisthotonus is occasionally seen; sometimes there are contractures of the extremities and even general convulsions.

Ulcers of the cornea are not uncommon.

These cases last from two months to a year. Comparatively few survive more than four months. Their progress is irregular and marked by exacerbations and remissions. They die most frequently in some of these exacerbations or from complications, but sometimes of the disease itself, by a slow asthenia.

Diagnosis.—The existence of a chronic diarrhœa can be determined beyond any doubt by an inspection of the stools, but in this way only. The problem usually presented to the physician is whether the condition of the bowels is of itself a sufficient explanation of the general symptoms, wasting, etc., or whether there is some underlying constitutional disorder of which the diarrhœa is only one of the symptoms.

In the primary cases this can be decided only by carefully weighing the etiological factors as well as the symptoms. If the disorder is traced to poor breast-milk, to bad habits of feeding, or to improper food, and if the general condition has been previously good, it is pretty safe to assume that the intestinal disease is the one of most importance. If, however, the infant has never thriven, or if nothing wrong can be discovered in either the food or the feeding, and if the wasting preceded by some time the intestinal symptoms, we must look for some other cause. Rickets, syphilis, tuberculosis, and simple marasmus must one after another be excluded, and the child examined carefully from head to foot for evidences of disease in the brain, lungs, liver, and spleen. Especially must chronic broncho-pneumonia be looked for. Malaria is a rare cause of chronic diarrhœa. It may be suspected if there is known exposure, with marked splenic enlargement.

In the secondary cases it is very important to distinguish the cases in which the cachexia is quite marked and convalescence slow, although ultimately resulting in complete recovery, from those which, although presenting at a certain stage symptoms almost identical with the preceding, yet go on from bad to worse, terminating in extreme wasting and in death.

The difference in these cases is really a difference in the character and extent of the lesions. The former are probably the cases of acute follicular entero-colitis which do not ulcerate, or those of the superficial catarrhal variety, lesions capable of being entirely or almost entirely recovered from. The latter group are the cases of follicular ulceration or those of the severe catarrhal form of inflammation, in which there is no such thing as complete recovery from the lesions, and the reparative process, if any occurs, is only partial and cicatricial.

In distinguishing between these cases the most important guide is the nature of the symptoms during the antecedent acute attack. The longer the acute febrile symptoms lasted, and the higher the temperature, the greater the extent of the lesions and the more severe their character. This applies particularly to the cases of the catarrhal variety. The diagnosis of follicular ulcers has been already discussed under the symptoms of acute entero-colitis.

In any case of chronic diarrhœa, the longer the symptoms have lasted and the more profound the cachexia, the greater is the probability of the existence of important lesions. As in the primary cases, a disproportion between the intestinal and the constitutional symptoms leads us to seek for some other cause for the latter.

It remains to consider the diagnosis of chronic diarrhœa with wasting, from tuberculosis. This may be confounded with either the primary or the secondary form of diarrhœa, but much more often with the latter. The difficulty is much increased by the fact that in the secondary cases tuberculosis is not an infrequent sequel to the intestinal disease, especially where a constitutional predisposition exists.

The points in common are the existence of diarrhœa (which occurs in almost all the cases of general tuberculosis in summer, apart from the existence of intestinal tuberculosis), the wasting, the anæmia, the cachexia, the signs of consolidation in the lungs, which in one case may depend upon broncho-pneumonia and in the other upon tubercular deposits, and the nervous symptoms,—those of chronic entero-colitis sometimes simulating very closely those of tubercular meningitis.

In simple entero-colitis both the previous condition of the child and the family history are more likely to be good than in tuberculosis. It is not to be understood, however, that the failure to obtain any history of tuberculosis in the family is to have any special weight in deciding this question. Tuberculosis is more likely to be met with in institutions and among the poor of cities than in the country. Yet how frequently this occurs among children in the country we do not know, from the fact that almost no autopsies are made there.

In chronic entero-colitis the wasting and anæmia follow the intestinal symptoms and are usually just in proportion to their severity; in tuberculosis we often see improvement in the intestinal symptoms and yet progressive anæmia and wasting.

The abdomen in entero-colitis is more frequently natural or retracted, while in tuberculosis it is oftener distended.

The spleen is rarely enlarged in entero-colitis; it is very frequently so in tuberculosis. The presence of marked enlargement is a strong point in favor of tuberculosis. A general enlargement of external glands makes entero-colitis much less probable than tuberculosis.

The cerebral symptoms of entero-colitis are, as a rule, less constant and less regular than those of tubercular meningitis, and rarely so profound. Localized paralyses are very common in meningitis; they are very rare, if indeed they ever occur, in entero-colitis. The fontanel in meningitis is tense and bulging; in entero-colitis it is depressed.

As regards the physical signs in the chest, broncho-pneumonia complicating chronic entero-colitis affects with great uniformity the posterior borders and lower lobes of both lungs. Pulmonary tuberculosis in infants has no regular distribution, but affects the upper lobes rather more frequently than the lower. The existence of much dry pleurisy renders tuberculosis more probable. If a cavity is found, this is almost conclusive, but not quite so. I have seen a non-tubercular cavity in a broncho-pneumonia secondary to entero-colitis.

Of single symptoms the most important differential one is fever. This is rarely absent in general tuberculosis, although its course is very irregular. If there is tubercular ulceration of the intestine, fever is probably always present. Fever is usually absent in chronic entero-colitis, except from complications, and from the occasional acute exacerbation.

It is by taking all the points of the case into consideration, rather than by reliance upon any single symptom, that the differential diagnosis is made.

Tuberculosis exists as a sequel of the cases of chronic entero-colitis very much more frequently than any one would imagine who does not have an opportunity to see the autopsies of the fatal cases.

Prognosis.—In general this depends upon the cause of the diarrhœa and upon our ability to remove it.

In the primary cases it is much worse among young infants than in those over two years old. It is worse when the symptoms have lasted some time and when they are continuous, better where they are intermittent. If there is some evident cause which can be removed,—such as improper food or feeding, or bad surroundings,—the prognosis is much better than when no cause is discoverable except the child's delicate constitution. It is worse when there is rickets, syphilis, or other constitutional vice. The existence of chronic diarrhœa increases the danger from any acute disease,—bronchitis, pneumonia, and the eruptive fevers,—and greatly adds to the liability to attacks of acute intestinal disease. It is, consequently, much more serious in summer than in winter.

In the secondary cases the prognosis depends upon the child's previous constitution, upon the duration of the intestinal symptoms, upon our ability to carry out proper treatment, like change of air, etc., upon the presence or absence of complications, but, most of all, upon the severity and extent of the intestinal lesions. The recognition of these has already been discussed under Diagnosis. The possibility of error always exists in estimating the gravity of the lesions, so that no case should be considered hopeless. Every physician who sees much of this form of disease has again and again met with cases so weak, so wasted, and so anæmic that recovery seemed out of the question; and yet after a few weeks under favorable circumstances they have begun to improve little by little and finally have gone on to complete recovery.

If, however, continuous symptoms have existed for eight or ten weeks without any sign of amelioration, recovery is very doubtful. There may be some improvement and the case may linger for two or three months longer, only to be carried off by the first attack of acute illness which occurs.

Treatment.—In the matter of prophylaxis there is only one point deserving special emphasis, and that is proper clothing for the feet and legs of infants at all times, and especially in fall and spring: in the winter they are generally sufficiently protected. The abdomen should be protected by a flannel band, except in midsummer. The other points in prophylaxis are sufficiently dwelt upon in the general section.

In the successful treatment of chronic diarrhœa, either in infants or in older children, almost everything depends upon general management, hygienic and dietetic, and almost nothing upon drugs. These cases are generally very much overdosed, greatly to their detriment.

In the primary cases in infancy we first seek to find and remove the cause. If it is poor breast-milk, the child must be weaned, unless a good wet-nurse can be obtained. If prolonged lactation is the cause, or pregnancy, nursing must be stopped at once. Proper food in these cases will often stop a very intractable diarrhœa in a few days without a dose of medicine, where all the routine of drug treatment has been gone over without the slightest benefit. In the same way, if the cause has been habitual overfeeding, improper food, or bad habits of feeding, it is useless to attempt to do anything by drugs unless the cause can first be removed. If there be associated rickets, syphilis, or malaria, these must receive their appropriate constitutional treatment.

In all cases in infancy rooms should be kept at an equable temperature in winter, and not too warm; plenty of fresh air must be allowed. There is no advantage in keeping the child in-doors unless it is extremely delicate or very young, or unless the weather is very cold or stormy. In going out it should be well protected, and the feet kept warm by a hot-water bag. In summer the child should certainly have the benefit of a change of air whenever this is possible. It should be sent from the city to the country, not merely for the sake of its chronic diarrhœa, but to escape as far as possible the dangers of acute attacks. The regions mentioned as proper for acute attacks are equally well suited to the chronic ones.

There should always be sufficient clothing to protect well the feet and legs.

The dietetic rules to be followed do not differ from those given for acute dyspeptic attacks after the first stage of severe symptoms has passed,—viz., breast-milk whenever it is possible; cow's milk used very sparingly, and never except it is well diluted or completely peptonized; if then the fat or curds appear in the stools as a constant thing, milk must be stopped altogether, and whey, broths, barley gruel, or some of the malted foods tried.

There is always a tendency to overfeeding, as these children's appetites are usually good and they will take almost any amount of food that is offered. Underfeeding is better than overfeeding. The object should be to maintain the nutrition of the child with the smallest irritation possible to the intestinal canal. We select our food, so far as we can, with this in view. Foods which leave the least residue are usually the best.

In older children an exclusive diet of boiled milk sometimes is exceedingly well borne. This may be thickened with barley flour or with "flour ball." As a rule, starches must be given rather sparingly, and combined with malt. If milk is not well borne, the animal broths, meat jelly, beef juice, and even raw scraped meat, may be tried. Monotony of diet is, if possible, to be avoided.

The use of drugs is of secondary importance: the routine use of opium and astringents, especially the tannin preparations, does more harm than good. We must husband our resources, and do nothing which would in any way disturb stomach-digestion. Antacids and aromatics are useful where there is acid fermentation of the stomach. An occasional cathartic dose of calomel or of castor oil, to sweep out the canal, is of great benefit. Pepsin, hydrochloric acid, and extractum pancreatis (Fairchild's) serve a very useful purpose. Opium is to be used occasionally when demanded by special symptoms, especially frequent watery movements, and also in cases where passages from the bowels follow almost immediately upon the ingestion of food.

Bismuth by the mouth is of value in the case of thin watery movements, but does less good when the movements are consistent and infrequent. I have little faith in the other mineral astringents.

Antiseptics are not of very great value in these chronic cases. If there is much flatulence, with offensive stools, these symptoms may be allayed often by salicylate of sodium or by salol.

Stimulants must be used in a very large proportion of the cases.

Irrigation of the bowel is of a certain amount of value, but much less than in most of the other varieties.

Arsenic and nux vomica are highly spoken of by Eustace Smith in many of these cases, especially during convalescence. I have rarely seen from their use the striking benefit of which he speaks.

In the secondary cases the treatment is virtually a continuance of the measures employed in the acute stage of entero-colitis. The children must be sent inland,—to the mountains if possible. The same dietetic rules apply as in more slow acute cases. Not much is to be expected from drugs. It is of no use to give these children week after week the various popular diarrhœa-mixtures, with the expectation that ultimately the formula which exactly meets the wants of the particular case will be found. The occasional use of opium is required by special symptoms,—*e.g.*, frequent thin movements. Bismuth is about the only other drug which can be said to have any influence on the lesion; but it must be given, as in acute cases, in large doses,—two to three drachms daily. Even bismuth should be stopped for a few days every week or two, to see how the stools are without it. An occasional dose of castor oil or of calomel is beneficial, and in a few cases the use of the smaller doses of oil (♏v to ♏x) in emulsion, four or five times daily, seems to be of advantage. It should not be continued more than two or three days unless very manifest improvement occurs, from the danger of disturbing the stomach.

Astringent enemata are of considerable value. We can hope to do very much more in the treatment of these lesions by this means than by drugs given by the mouth. Enemata should be used once a day, but should be discontinued for a few days every week or two, to see what the condition of the stools is without them. In using these the method should be practised, already described in the treatment of acute cases, of first irrigating the whole colon thoroughly with either plain lukewarm water, or a salt solution (a teaspoonful to a pint), or a borax solution of the same strength. In this way mucus, fæcal matters, etc., can be removed, and the astringent solution brought in direct contact with the mucous membrane.

The astringents to be used are tannic acid, bismuth, and nitrate of silver, their ratio of value being in the order named. The same strength of solution as in the acute cases may be employed. They should be lukewarm, or they will be quickly expelled. Where irrigation and astringent enema are to be used for a long time, as several weeks, there is a decided advantage in changing the astringent every week or ten days.

Complications should always be watched for: they are to be treated on general principles as they arise.

In some of the secondary cases, especially if the symptoms have lasted eight or ten weeks with little or no change, we get the best results by directing our entire efforts towards the general cachexia and stopping all intestinal therapeutics. Alcoholic stimulants must be used in almost all cases, and they may be kept up for a long time with advantage. Old port or sherry will sometimes do better than brandy or whiskey. Usually we give that which the patient will take most readily. The predigested foods are of much value; so also are the beef preparations, bovinine, beef peptonoids, and meat extracts; raw meat may be used with benefit.

Massage is also of real value in some of these cases. Inunctions of cod-liver oil may be used, or other forms of fat.

Where there is a failure in the absorption of fats, I have seen beneficial results follow Reed & Carnrick's combination of pancreatin and bile known as pancrobiline. It is given in pills coated with keratin to older children from one and a half to two hours after feeding. In infants the liquid preparation may be substituted, half a drachm to a drachm being given one hour after feeding, not more than three times a day.

In general, in the treatment of the secondary cases of chronic diarrhœa the patient must first be put in the best possible surroundings,—in no cases does a change of air do more; minute and careful attention must be given to diet, and the effects studied by the stools and the weight; in respect to diet each case must be studied by itself; intestinal irrigation offers much better chances of success in treating the lesions than drugs by the mouth; it is sometimes better to ignore the intestinal lesions and seek to promote the general nutrition by all possible means. These cases are always trying ones to the physician. Unless he can control absolutely the matter of diet, it is hopeless to attempt to do anything. Still, by careful study of the individual case, and minute attention to details, especially in dietetics, success may sometimes be achieved even in the cases which seemed at the outset the most desperate.

The danger of relapses and second attacks continues for many months. During the summer following such an attack, the child should be sent where it will be least likely to suffer from further attacks of diarrhœa.

MEMBRANOUS ENTERITIS.

By WILLIAM A. EDWARDS, M.D.

Synonymes.—Pellicular colitis, Intestinal cast, Pseudo-membranous enteritis, Intestinal desquamative catarrh, Mucous disease, Chronic muco-colitis, Chronic croup of the intestines, Chronic pellicular inflammation of the intestinal mucous membrane, Fibrinous diarrhœa, Follicular, Duodenal, and Colonic dyspepsia, Chronic pseudo-membranous gastro-enteritis, Tubular looseness, Tubular exudation-casts of the intestine, Mucous or Gelatinous diarrhœa, Mucous casts; Latin, Diarrhœa febrilis, Diarrhœa tubularis, Hypochondriasis pituitosa; French, Entérite interstitielle.

The term membranous enteritis has within the last few years become restricted in its application to a particular form of intestinal disorder, characterized by irregularly recurring paroxysms of abdominal pain, unaccompanied by fever and relieved by the passage of membranous shreds or tubes, which for the most part are composed of mucin. In this article it is not our purpose to deal with cases in which the passage of the membrane is accompanied by all the symptoms and concomitants of enteritis or entero-colitis in their acute or chronic form, but rather with cases in which the passage of the membrane is about the only symptom presented, or at least is the most marked feature of the disorder.

It has been recognized for many years that a mucous substance may be voided by stool, but it is only recently that these cases have received careful attention and proper classification. At first these membranous shreds and tubes were considered to be portions of the intestinal canal, but Fernelius in 1554, Van Swieten, and Sennertus all recognized their true nature and so recorded them. Still later Morgagni further described the disease; he considered the membranes to be due to the fact that the pituitous humor became concrete and adhered to the inner coat of the intestine. Within the last few years able and careful papers have been written by several observers, to which I have already called attention.[1]

Etiology.—The most varied and opposite etiological factors have been adduced in endeavoring to arrive at a true understanding of the causative agents in producing the condition sometimes styled tubular diarrhœa, a not inapt designation. We, however, definitely know that climate, occupation, and inheritance are not to be considered as predisposing causes of the disease.

---

[1] Amer. Jour. of Med. Sci., April, 1888.

It is undoubtedly a fact that most cases occur in young adult females who are hysterical, or at least of a nervous disposition; but recently sufficient cases have been recorded among children to merit consideration in a work such as this, remembering, however, that the disease is not a frequent one in children. In one hundred and eleven cases six were under the age of ten.

Clemens[1] reports four cases as occurring in children; Chapin[2] records other cases, as does also J. Lewis Smith;[3] Whitehead[4] adds two children to the list. Laget[5] has observed an infant convalescing from diphtheria who passed a mucous cast nearly eight inches long, and Barrier[6] an example of the disease in a child of five years.

Sex.—Sex does not seem to be the same predisposing element in children that it undoubtedly is in adults, when we can say that the majority of cases are seen in hysterical women; for example, eighty per cent. of the recorded adult cases occurred among females.

The disease is apt to be either a concomitant or a sequel of disease of the genital or the intestinal tract or of the nervous system: most observers report an antecedent dyspepsia and constipation alternating with diarrhœa. Grantham has considered the abuse of mercury to be productive of the condition. In a child it may follow typhoid fever, enteralgia, hemorrhoids, or tuberculosis of the intestine.

We must exclude from consideration the membranes passed in the so-called croupous or diphtheritic enteritis, as it has not been allotted to us to consider all forms of membranes passed, but simply that form which is purely a mucous cast.

Da Costa attributes the etiology to the nerves presiding over nutrition and secretion, considering the disease to be a manifestation of disordered nervous supply, which may be either general or local. Wales considers the ganglionic nerves of the intestine to be primarily at fault; most cases will certainly present marked evidences of deranged nervous action.

Symptoms.—The passage of the casts is usually paroxysmal, accompanied by abdominal pain, tenesmus, and nervous disturbances, and preceded or followed by digestive troubles. Abdominal tenderness almost always exists, and is generally relieved by the passage of the membranes; blood may be present in the discharges; at this time the bladder will usually present some symptoms or evidences of sympathizing in the disorder, more particularly should the disease occur in a female at or after puberty, when manifestations of uterine disorder will be almost invariably present.

Patients who are the subjects of membranous enteritis, while they do not lose the normal contour of the body, still present some evidences of malnutrition. They are apt to have eruptions of furuncles and carbuncles, sore mouth, or herpes of the genitals, and an irritable nervous system. Emaciation is rarely a marked symptom: indeed, it is worth noting that this almost complete lack of emaciation persists throughout the course of the disease, notwithstanding the amount of matter passed.

The number of paroxysms is very variable: patients are sometimes able to foretell an attack by certain symptoms, as chilliness, blueness of the nails, and tingling or pain at the finger-tips. A person the subject of this disease may suffer but one attack in a year, or but one a month, or, on the other hand, the paroxysms may be continuous, as in one of my own cases. The duration of the attacks is also very variable: they have been reported as short as twenty-four hours and as long as two weeks. The difficulty of precisely limiting the attack will be appreciated when it is remembered that in the more chronic cases there is an almost constant sequence of symptoms. It must also be borne in mind that the patients are usually dyspeptic and suffer more or less from constipation and from abdominal distress which sometimes amounts to severe pain referred to the umbilical region; indeed, this train of symptoms usually precedes for some time the expulsion of the membranes. Membranes are not found in each stool during a paroxysm, as a rule, but a single accumulation is generally passed, accompanied by pain and tenesmus; indeed, some cases discharge the membranes only about once a week; on the other hand, patients may have ten or a dozen membranous stools in twenty-four hours.

Pain, tenderness, and tenesmus are complained of in varying degrees by different patients. The most usual manifestation is abdominal pain, which may be simply a sense of uneasiness or may be agonizing pain which is generally relieved by the passage of the membrane. Tenderness may exist over the entire abdomen, or may be localized and developed only by firm pressure.

Hemorrhoids, prolapse of the rectum, diarrhœa, jaundice, extreme thirst, coated, anæmic, and fissured tongue, aphthous ulcer of the mouth, and tonsillar phagedæna have all been noted in the symptomatology of the disease.

The nervous system presents many and varied manifestations. To some of these neuroses we have already called attention, particularly the hysterical derangements, which are the most frequent of all the functional disturbances. The following symptoms have been noted: neuralgia, hyperæsthesia, anæsthesia, irregular muscular tremors, paresis, hysterical tetanus, and coma; convulsions have also been observed. Transient defects in vision, tinnitus aurium, and disordered sense of taste are also among the recorded symptoms.

Whitehead has noted chorea and paralysis, and Copeland has observed a cataleptic condition, follow an hysterical outbreak. Cerebral symptoms have occasionally appeared: for instance, amnesic aphasia has been recorded; mental depression, faulty memory, hypochondriasis, and melancholia may be exhibited for a time, to be followed possibly by increased mental activity.

The temperature is rarely above normal, except possibly during the height of a paroxysm which is accompanied by much pain; it may, however, be affected by an intercurrent disease, as phthisis.

Microscopic Appearance of the Membranes.[1]—They are for the most part made up of opaque white, solid masses, rounded or flattened, and small flocculent pieces of semi-translucent membrane; the membranes are delicate, and out of water are handled only with the greatest difficulty.

Under a ten-inch objective their surface is seen to be composed of opaque and translucent parts, the former apparent as rounded ridges marking off the latter into regularly-arranged hexagonal or polygonal crypts; under a higher power these crypts are still visible, although much less defined. These appearances are seen best in small flakes of membrane, less distinctly in the larger masses, and not at all in the finer net-works that are sometimes passed.

These masses of membranes appear to be due to the formation of mucous and epithelial matter either upon the surface of or in contact with some follicular mucous membrane. This view is evidenced by the nomenclature of the Philadelphia Pathological Society, which, for example, considers the membranes to be the product of an "interstitial desquamative catarrh." On comparison of these membranes which are moulded by the gut with the healthy mucous membrane, certain differences are at once apparent: the mouths of the pseudo-follicles on the surface of the cast are much larger than those in the normal intestine; they approach closer to one another, and may run one into the other; the cells present in the membrane have no definite arrangement, and are not placed upon a basement-membrane, which is entirely absent in the mucous formations. The cells have undergone a fatty disintegration.

Mills and Clark tell us that, upon laying the cast open and examining its inner surface under a power of forty diameters, a gelatinous membrane-formed matrix was observed, traversed by a coarse net-work of opaque yellow lines and studded at other points of intersection by similarly-colored roundish masses; from the large net-work proceeded a smaller net-work, and in its meshes were formed, at close and regular intervals, well-defined oval or round openings, with elevated margins, looking like the mouths of the follicles in the large bowel. Under a power of three hundred and fifty diameters the matrix was transparent, structureless, elastic, and everywhere free from fibrillation. Embedded in it were granules, free nuclei, cells, crystals, and particles of undigested food. The opaque yellow lines were seen to be composed of foreign matters, as bile-pigment, earthy and fatty granules, portions of husks of seeds, gritty tissue of pear, a peculiar form of elastic tissue, stellate vegetable hairs, and a mucedinous fungus. The cells in the matrix were either spherical or cylindrical,—in some portions lying without obvious order, in other parts arranged in layers. Generally the membranes consisted of a single layer of matrix with cells, but in some places several layers of matrix could be noted.

---

[1] Specimens of the membranes are preserved in several museums, to which I have referred in a communication to the Philadelphia Medical News, August 7, 1886.

Andrew Clark, in a supplementary note, takes exception to the above report. After citing several propositions to prove his hypothesis, he concludes that he is justified in stating that the casts or membranes are not fibrinous, that they are not the product of inflammation in the sense defined (chronic inflammatory action of the mucous membrane, and subsequent exudation), and that the abnormal cell-products have arisen in some other way —*i.e.*, metamorphosis—than by free development of an exuded blastema. He also makes the further observation, which is of extreme interest in the present study,—viz.: the product of diseased action in mucous membranes occurs in three varieties: first, clear, jelly-like, and imperfectly membranous; second, yellowish, semi-opaque, flaky, and usually membranous; third, yellowish white, dense, opaque, distinctly membranous, tough, and rather adherent to the subjacent surface.

Action with Reagents.—H. B. Hare states that pharyngeal mucus, for example, will exhibit chemical reactions similar to those of the membranous discharges, and states, further, that the discharges consist essentially of mucin, with possibly a trace of albumen, and no fibrin,—thus confirming my own views on the subject and agreeing for the most part with all other observers.

Strong acids and alkaline solutions of moderate strength will dissolve the casts. Their albuminous nature is further shown by acting on these solutions with the usual tests for albumen,—heat and nitric or acetic acid. Some observers (Clark) have noted the absence of albumen in the membranes.

According to Goodhart, after the solution has been precipitated it cannot be reprecipitated by acetic acid, ferrocyanide of potassium, alcohol, ether, or perchloride of mercury. The casts stain readily but irregularly with carmine.

Pathology.—The colon seems to be generally the selective site of the disease; this, however, is not always the case, as the small intestine may be invaded, either in conjunction with the colonic deposit or altogether independently of it. Upon referring to the literature of the subject, one is at once struck with the extreme paucity of post-mortem records of the disease; and if we exclude all cases of croupous or diphtheritic deposit the number becomes small indeed.

Simpson says that Abercrombie saw a case in which the mucous membrane of the colon was covered by an immense number of clear white spots, which were small vesicles that when punctured discharged a small quantity of clear fluid; the patient during life had passed a large quantity of membranous casts or tubes. The small intestine was healthy. The girl died of phthisis.

Da Costa is of the opinion that the affection is not originally an inflammation, considering the inflammatory element to be the result rather than the cause. Clark held that the membranes were not the product of inflammatory action, because they contained no fibrin, a view that is not tenable at the present day, because we know that fibrin is not an essential component of an exudate. My own views are in accord with the general opinion that if inflammation is present at all it is in a very mild form. Siredey, Wales, and Whitehead all practically agree that the pathogenesis of the affection is to be looked for in the nervous system; indeed, as Da Costa aptly remarks, "the association often with similar discharges from other outlets points to a deeper, more general cause than enteritis or a morbid condition of the intestinal mucous follicles." Barrier noted alteration in the follicular apparatus of the intestine.

Diagnosis.—The diagnosis of this condition presents few, if any, difficulties. If mistakes arise they are, in all probability, due to the carelessness of the observer rather than to any obscurity in the manifestations of the usual clinical phenomena of the disease. The writer has known observers to consider the membranes to be ascaris lumbricoides: the resemblance in some cases is close, indeed, but they are readily distinguished by even a casual examination. Again, the white, shining, detached pieces have been mistaken for segments of tænia mediocanellata, tænia solium, and bothriocephalus latus; but, as above stated, the failure to recognize the nature of the disease is not on account of its atypical manifestations. It has also been mistaken for fatty discharges and for the lienteric discharges of dysentery. Anal fissure may cause a hypersecretion of mucus.

In cholera a fibrinous or gelatinous matter has been noticed in the small intestine; in some cases this has taken the form of a croupous deposit. In scarlatina and in tubercular disease a membrane occasionally forms and is cast off.

That adult patients may inadvertently be misled, and thus mislead their medical adviser in relating the history of their complaint, is proved by the experience of Quekett, quoted by Richard Quain, who records the case of a patient who at intervals of two or three weeks had severe abdominal pain, occurring in paroxysms, always relieved by the passage of a mass, sometimes as large as an orange, or larger, made up of membranous matters and tubes. The mass represented the undigested portion of mutton-chops upon which the patient had been living. Quekett further states that he has observed nine cases of a similar character. Schubler[1] gives a plate illustrating peculiar branching tubes passed per rectum, which were also probably the arteries and ligaments derived from the meat diet of the patient; and similar cases are reported by Elsässer and Uhl. In other cases the membranes appear to be made up entirely of yellow elastic tissue which, according to Corrigan,[1] resembles closely the ligamentum nuchæ of sheep.

In conclusion, portions of the gut itself[2] or its necrosed mucous membrane may be voided by stool; but the history of the case, and the constitutional condition of the patient, with the concomitants and the appearance of the matter passed, should quickly elucidate the nature of the disease.

Prognosis.—The prognosis in relation to cure is bad: most cases run a prolonged and tedious course, in many patients extending over the larger part of adult life. The disease of itself, uncomplicated, rarely proves fatal; the recorded causes of death are totally independent of the membranous affection.

Treatment.—We may consider the treatment under two headings,—the prophylactic and the active, or that which is appropriate during an interval or remission, and that which we resort to during an exacerbation. It is during the intermissions that we can hope to do more for our patient's permanent good than during an actual attack: it is then that diet, regimen, and hygiene are of greatest importance. There must be a careful supervision of the patient's daily life. All sources of irritation are to be removed. Easily-digested or even pre-digested food should be supplied, and care should be taken to ascertain that undigested particles of food are not irritating the intestinal canal. As constipation usually exists, sometimes to a stubborn degree, mild saline laxatives are generally most efficacious; enemata or glycerin suppositories may be resorted to.

During the acute stage of an attack opium will often be found necessary to afford relief, and possibly to check excessive secretion or hemorrhage. Belladonna in the form of extract, Dover's powder, and subnitrate and subcarbonate of bismuth, with local counter-irritation, all tend to abort the paroxysm or at least to shorten its duration. The following remedies have been suggested: arsenic, copaiba, bromide of potassium, nitromuriatic acid, henbane, vegetable infusions, prolonged counter-irritation, electricity, turpentine, iron, cod-liver oil, oxide or nitrate of silver by mouth or by high injection into the bowel, chloride of ammonium, sulphate of zinc, bichloride of mercury, chlorate of potassium, oxide of zinc, blisters, warm-water enemata, nux vomica, ergot.

Exercise for the growing child who is robust enough to bear it is of paramount importance, and, if possible, should be out of doors: hence a mild, equable climate should be selected for the little patient, one in which he may pass the greatest number of days in clear sunshine and surrounded by a balmy atmosphere.

INTESTINAL BACTERIA OF CHILDREN.

By WILLIAM D. BOOKER, M.D.

Definition.—Bacteria are small, globular, rod-shaped or spiral, unicellular organisms, which increase by transverse division. Bacteria are divided into micrococci, bacilli, and spirilla. Micrococci are spherical or slightly oval, no difference being recognized in length and in breadth. Bacilli are rod-shaped, the length exceeding the breadth. Bacilli curved on the long axis are called comma bacilli, and a chain of them constitutes a spirillum. But there are also spirilla, or long spiral threads, which show no division into commas. The same species of bacillus may show considerable variation in the length and size of individual rods, but there is no satisfactory evidence to prove that a bacillus changes into a micrococcus, or a micrococcus into a bacillus.[1]

History.—The occurrence of bacteria in the fæces has been known for many years, but no practical advantage was derived from this knowledge until the recent introduction, by Koch, of methods for isolating bacteria and studying their biological characters. Application of these methods to the study of intestinal bacteria in children has within the past five years brought to light information of great interest and value. It must be remembered, however, that this study is complex and extensive, but still in its infancy, and that further investigation may modify many of the views now held.

Bacteria in the fæces of children living upon a mixed diet differ greatly in number and in kind from those in the healthy fæces of milk-fed infants. The biological study of intestinal bacteria in children has been confined chiefly to the latter, to the bacteria in the meconium, and to those in the dejecta of infants affected with summer diarrhœa.

Bacteria were first observed in the fæces in 1719 by Anthony van Leeuwenhoek,[2] a private citizen of Holland: they were found by him in the fæces of various animals and in his own diarrhœal fæces. Leeuwenhoek attached no importance to these small organisms, but some of his contemporaries regarded them as a cause of a number of diseases. This opinion, unsupported by experimental evidence, was soon abandoned, and no further attention was given to the subject until about the middle of the present century.

---

[1] As bacteriology has become a subject of so great importance to the physician and surgeon, and especially to those who see much of children's diseases, it has been fully treated of in vol. i., and thither the reader is referred for an account of methods for cultivating and studying the characteristics of bacteria.

[2] Contemplationes Antonii de Leeuwenhoek, Opera Omnia, tom. i., 1719, Epistola ad Regiæ Societatis Collegium Londinense Robertum Hooke.

In an article published in 1845, Gros[1] states that human excrements, whether healthy or diseased, swarm with vibrios of various sizes.

Frerichs,[2] in his celebrated article on digestion published in 1846 in Wagner's "Handwörterbuch," devoted a special section to the micro-organisms found in the alimentary canal, and described the morphology of the most striking forms seen by him. He regarded them as having little or no effect upon digestion, being harmless invaders which thrive and grow in the intestine because it affords a favorable soil.

Greater interest was given to the subject of intestinal bacteria, as of bacteria in general, by Pasteur's demonstration in 1857 that these organisms are capable of exciting profound chemical changes in the nature of fermentation and putrefaction, and the discovery by him and others that certain infectious diseases are caused by bacteria. Proceeding from the latter point of view, Hausmann,[3] Klebs,[4] Billroth,[5] Woodward,[6] and others directed their attention to a microscopical study of the bacteria found in the intestinal canal and the fæces of healthy adults.

Woodward carefully described the morphology of the bacteria found in the normal and diarrhœal fæces. He recognized a difference in the size and quantity of the bacteria in the normal and the pathological fæces, but, owing to their similarity, he was not able to establish a relation between individual forms of bacteria and definite diseases. He also recognized that similarity of form was not sufficient to prove an identity.

Hoppe-Seyler, Nencki, Fitz, Brefeld, Senator, and others undertook the investigation of the fermentative action of the intestinal bacteria, but, as their experiments were made with the mixed bacteria of the fæces, without reference to their purity, no definite conclusions could be reached.

Both Pasteur and Duclaux,[7] although on insufficient data, expressed the opinion that great importance is to be attached to the *rôle* of micro-organisms in the work of digestion. Nothnagel[8] in 1881 was the first to attempt to identify the various species of micro-organisms found in the fæces, according to their morphological peculiarities. He did not, however, isolate them by cultivation.

Brieger,[1] Bienstock,[2] and Stahl[3] were the first to take advantage of the modern methods for isolating bacteria and to attempt to establish the relation of the individual species of bacteria found in the fæces to definite fermentative processes. Brieger isolated from the normal fæces two species of bacteria possessing fermentative properties, one fermenting grape- and cane-sugar into ethyl alcohol, the other forming propionic acid out of grape-sugar.

Bienstock separated from the fæces a species of bacterium found in large quantity, which he considered to be capable of splitting albuminous compounds into their ultimate products. Besides this species Bienstock isolated three other bacilli, and arrived at the conclusion that these four species of bacilli are the only bacteria existing in the healthy intestinal canal with the administration of a mixed diet,—a conclusion in direct contradiction to that of all other observers.

Stahl, who was about the same time engaged in the systematic isolation of the bacteria of the adult fæces, found twenty different species of bacteria. This valuable work was, unfortunately, left incomplete by the death of its author, and no mention is made of the relation of these bacteria to fermentation.

Miller[4] isolated twenty-five varieties of bacteria from the mouth of adults, eight of which were again found in the stomach and twelve in the intestine. He also found that a considerable number of these varieties produce lactic-acid fermentation in carbohydrate solution, that a peptonizing action was shown by a majority, and that only a few varieties possess a diastatic action.

The preceding citations refer only to the investigations made upon adults.

Löschner and Lambl made the first special reference to the occurrence of vegetable parasites in the intestinal contents and fæces of children, in the report of the Franz-Joseph's Hospital in 1860. The report refers only to pathological cases.

Widerhofer[5] observed bacteria, especially leptothrix-like forms, frequently in the diarrhœal dejecta, and predicted that future investigation would bring one or other form into accidental or essential connection with special intestinal diseases. Demme[1] repeatedly refers, in his reports of the Basel Children's Hospital, to the remarkable fact that even in the fæces of healthy children a large quantity of bacteria, especially rod forms, are found.

In spite of these statements, so little was generally known on the subject that Johnstone, even in 1881, drew the conclusion that the occurrence of bacteria in the stools of children affected with summer diarrhœa in the city of Leicester was due to an infection from the sewers, in which the bacteria were likewise found in great numbers.

Baginsky attempted, by means of a microscopical study of the diarrhœal dejecta and pathologico-anatomical examination, to establish the relation of bacteria to the etiology of summer diarrhœa in children. In his valuable work[2] he described the morphology of a number of bacteria and fungi: one form, a narrow bacillus, he found almost constantly in cholera infantum, and attached some importance to it. He became convinced, however, that no reliable information could be obtained by this method of research.

While these and many other investigations had been carried on with the diarrhœal fæces, the study of the bacteria in the normal fæces of children had been neglected to an astonishing degree.

Uffelmann[3] was the first to recognize this, and to realize that progress in the diagnosis and therapy of summer diarrhœa in children must be founded upon a chemical and microscopical study of the stools of healthy breast-fed children. (In 1842 Franz Simon made a chemical analysis of the fæces of healthy breast-fed children, and the subject was again taken up by Wegscheider in 1875, but neither made any reference to bacteria.) Uffelmann found the great mass of the fæces of healthy sucklings to be composed of micrococci and rod bacteria, the latter greatly predominating.

We owe to Escherich the fundamental investigation of the bacteria in the contents of the intestine and stools of healthy sucklings. His researches, made according to the most approved bacteriological methods, are of great value, and have laid the foundation for a fruitful study of the bacteria in the pathological stools of infants. Our information upon the bacteria in the meconium and healthy fæces of sucklings has been derived almost exclusively from his work.[4]

The Entrance of Bacteria into the Intestine.—The chief mode of ingress of bacteria to the intestine is through the air, the saliva, and the food which is swallowed, but, inasmuch as bacteria are sometimes found in the meconium taken from the rectum three to seven hours after birth, they may, no doubt, enter also per anum. To what extent the gastric juice prevents the entrance of bacteria into the intestine is not definitely known. According to the investigations of Miller,[1] the gastric juice is not destructive to bacteria if the hydrochloric acid is in less proportion than 1.6 to 1000. Miller's observations led him to believe that the gastric juice does not hinder the greater portion of bacteria from entering the intestine, and that all the bacteria examined by him could pass through the stomach if swallowed at the beginning of the meal, but swallowed at the height of digestion the gastric juice was then more injurious. Busch observed in a case of intestinal fistula in a woman portions of the food in the intestine in from fifteen to twenty minutes after beginning the meal, and liquid and pulpy foods pass into the intestine sooner. Moreover, in pathological conditions of the stomach, when the gastric juice is not secreted normally and the hydrochloric acid is abnormally diminished, it may have little or no effect upon the bacteria. The development of bacteria in the intestine is dependent in large measure upon the nutritive media found in the intestine.

Method for Collecting Intestinal Bacteria.—Bacteria are collected from the healthy fæces by causing an evacuation by the introduction of a sterilized glass rod or syringe-nozzle into the rectum, after having first washed the anus with sublimate solution and then with sterilized water. As soon as the fæces are passed an opening is made on the surface of the mass with a heated knife, and a sterilized curved platinum needle introduced through the opening into the interior, from which small portions are taken up and put into sterilized test-tubes containing bouillon. Plate-cultures or Esmarch tubes are then made from the bouillon-cultures as soon as possible. From the contents of the intestine bacteria are similarly collected by cutting an opening in the wall of the intestine with heated scissors, through which the platinum needle is introduced. Bacteria are collected from the liquid diarrhœal fæces by introducing a small sterilized glass tube into the rectum, or, better, a larger sterilized tube first introduced through the anal opening and the smaller tube inserted through it into the rectum. In a short time a discharge from the bowels is produced, filling the inner tube, which is first withdrawn and emptied at once into the test-tube containing bouillon. The small tubes are conveniently kept ready for use in sterilized test-tubes.

Meconium Bacteria.—Escherich proved the correctness of the common belief that the meconium of the new-born infant is entirely free from micro-organisms. After a variable period bacteria make their appearance in the meconium, and usually by the second day after birth are present in large numbers. According to the observations made by Breslau[2] in 1866, the quick infection of the meconium takes place through the air which is swallowed, even before food is taken. Breslau observed that as soon as breathing begins the child makes sucking and swallowing movements, and by means of percussion and a series of autopsies he found that air reaches the stomach and upper part of the duodenum in a few hours after birth. The air is carried through the intestine by peristalsis, and in twelve hours is perceptible over the greater part of the small intestine, and in twenty-four hours over the large intestine and the rectum. Escherich found bacteria in many cases in the meconium taken from the rectum from three to seven hours after birth, and believes that this can be accounted for only by the entrance of the bacteria per anum. As the meconium is infected from the germs in the surrounding air, it is evident that the varieties of bacteria and quickness of infection will depend upon the varieties and quantity of bacteria in the air. This is influenced by location, season of the year, and temperature. In the summer and in the city we may expect a richer vegetation in the meconium in twenty-four hours than in the winter and in the country. Tompkins found that the air in the diarrhœal districts of the city of Leicester contained five times more bacteria than the air in districts not affected with diarrhœa. Not only is there a great difference in the time of appearance, but also in the varieties and quantity of bacteria in the meconium.

---

[1] Deutsche Med. Wochenschr., 1885, xii. 3.

[2] Zeitschr. f. Geburtskunde, 1886.

If the meconium is examined from three to seven hours after birth it is either sterile or contains only micrococci, mostly in the form of large diplococci. After eighteen hours, in most cases, rod-form bacteria are found. The micrococci are of relatively large size and great variety. The bacilli are also of manifold variety. Two spore-bearing species are especially noticeable, one of which belongs to the so-called head bacillus, consisting of a slender filament from four to seven micro-millimetres long, in which a glistening spore is set, the other appearing identical with the bacillus subtilis. Besides these forms are to be mentioned large circular or elliptical budding spores. As Escherich found in two such widely separated places as Munich and Vienna almost the same forms of bacteria in the meconium, especially the spore-bearing bacilli and micrococci, he thinks that, besides the accidental moment of air infection, a certain relation exists to the nutritive media in the meconium which affords a favorable condition for only certain kinds of bacteria. This he thinks is also shown in a negative sense by the disappearance of the rich and well-developed bacterial vegetation with the complete discharge of the meconium. Escherich had the opportunity of examining the last remnants of the meconium and the beginning of the milk fæces which were passed at the same time. In the first portion, which was shown by microscopical examination to be composed of the meconium almost exclusively, the head-form bacilli, a few short rods, and micrococci were found; while in the second portion, composed of milk fæces, no head-form bacteria or other forms belonging to the meconium were seen,—only the forms belonging to the milk fæces in sparse quantity.

This astonishing and easily-proved fact—*i.e.*, the change of bacterial vegetation with the beginning of milk nourishment—is of great importance to the knowledge of the conditions prevailing in intestinal putrefaction. It seems to be the first direct proof of the dependence of the bacterial vegetation of the intestinal canal upon the chemical composition of the intestinal contents. The milk in the intestinal canal not containing all the ingredients necessary for the development of the meconium bacteria, they disappear and give place to other species. The disappearance of the meconium bacteria with the entrance of milk diet may be explained according to the observation of Nägeli, that the fermentation of bacteria is not merely advantageous to themselves but at the same time injurious to other species,—not through withdrawal of nourishment or secretion of injurious compounds, but through the presence of special fermentation.

Culture experiments distinguish two periods in the relation of bacteria to the meconium. The first meconium, as in the fœtal condition, is still free from germs, or contains merely a few micrococci and germinating fungi which occur frequently in the surrounding air. These represent the microorganisms entering per anum. The second period is when the upper meconium column, early infected with germs from the air taken in per os, appears in the rectum. Here we find a tolerably rich and manifold variety. The difference between the bacterial vegetation of the meconium and that of the subsequent milk fæces consists in the meconium containing a smaller number of individual bacteria but a greater variety of forms, among which micrococci and certain spore-bearing bacilli are especially numerous.

Intestinal Bacteria of the Healthy Suckling.—A microscopical examination of the healthy fæces of sucklings shows it to be composed chiefly of bacteria, containing a larger number than the fæces of the adult and a much larger number than the meconium. This may be explained by the fact that the fæces of sucklings contain a larger proportion of water. A further comparison of the microscopical appearance of the healthy fæces of sucklings with the healthy fæces of adults gives the astonishing similarity of bacteria in the former in place of the manifold variety in the latter. While bacteria are present in enormous numbers in the fæces of healthy milk-fed infants, it was found that two species of bacteria are constantly present, and that of these one species so greatly predominates that it is sometimes found almost as a pure culture. The bacteria constantly present are the bacterium lactis aërogenes and the bacterium coli commune. These are designated obligatory milk-fæces bacteria, in distinction from the inconstant bacteria, which are called facultative or potential milk-fæces bacteria. The latter are found in small number and without regularity or frequency. Among them micrococci are generally but not always found, and only in small number. Long spore-bearing threads, free spores, spirals, and comma forms have not been observed.

In a systematic examination of the contents of the healthy gastro-intestinal canal of sucklings, it has been found that the stomach contains a very sparse vegetation composed chiefly of rod forms, the upper part of the duodenum a few round or short rod-like forms, but at the end of the upper third of the small intestine the vegetation becomes richer and contains diplococci, bacteria lactis aërogenes, and colon bacteria. The latter increase in number and in the length of the individual bacteria in the lower part of the small intestine, but the bacteria lactis aërogenes undergo no further increase. In the cæcum there is a great increase of colon bacteria, and this continues throughout the colon, with an increase also in the length of the bacteria. The number of bacteria found in different sections of the intestine appears to depend upon the quantity of undigested food present and upon the length of time it remains there. The upper part of the duodenum, containing chiefly secretions and little or no food, is found, at least microscopically, to be almost free from bacteria. Here we have a large quantity of secretions free from bacteria, mixed with a small quantity of food containing them, which is removed by the active peristalsis of this part of the intestine before any considerable development of bacteria can take place. In the colon, where the food remains a longer time, the bacterial vegetation is correspondingly great. The increase in the length of the individual bacteria is ascribed to a preponderance of the older, well-grown forms or to the increasing exhaustion of the nutritive media (Buchner).

The inconstant or potential milk-fæces bacteria are found in larger number in the large intestine, and not at all, or only in small quantity, in the small intestine. There is found, then, not only a difference in the number and size of the bacteria in the upper and the lower part of the intestine, but also a difference in the variety of bacteria.

Our present bacteriological methods do not enable us to isolate in the form of pure cultures all of the bacteria existing in the fæces. There is, therefore, a discrepancy between the results of microscopical and those of bacteriological examination of the fæces, the latter method showing a smaller variety of organisms than the former. For this reason, if for no other, it is plain that the bacteriological cannot displace the microscopical examination. The two methods must be used in combination with each other. Efforts to obtain culture-media more suitable than those in common use for the cultivation of a large number of fæcal bacteria have not been successful. According to the investigations of Buchner[1] and Kuisl, the vital energy of some of the bacteria is weakened through injurious influences acting upon them in the intestinal canal. All of the bacteria, however, are not thus affected. Buchner believes that the normal intestinal ferments act injuriously upon bacteria. But it has been shown that none of the normal secretions of the digestive tract except the acid gastric juice have an injurious effect upon bacteria. It is more probable that many of the varieties of bacteria which enter the intestine fail to find suitable conditions for their development.

The antagonistic action which is known to exist between many different varieties of bacteria when planted together may also assist in clearing up the discrepancy between the number and kind of organisms found microscopically and by the culture methods.

Biological Characters of the Obligatory Milk-Fæces Bacteria.—*Bacterium Lactis Aërogenes.—Morphology.*—Short thick rods with rounded ends, often joined in pairs. Average size from one to two micro-millimetres long and one-half to one micro-millimetre wide. The short forms sometimes appear oval or almost round. In cultures eight days old the bacilli are longer than in fresh cultures, and many show when stained with gentian violet a deep violet centre with purple or clear poles. The bacilli show no motion of their own, and have not been found to contain spores.

Bacterium lactis aërogenes grows readily on the ordinary culture-media. In gelatin cultures the colonies develop rapidly, grow more in height, and do not spread extensively over the surface. They are generally round, with even borders, though often irregular in shape, white to the naked eye, and seen under the microscope have a yellow or yellowish-brown appearance. In stab cultures the surface growth is white, raised, and extends uniformly a short distance from the point of inoculation. Along the line of inoculation in the depth is a solid stalk, with sometimes a marked swelling at the end. Some stick cultures show the nail-form growth. On potato the culture is whitish yellow or cream-colored, thick, of pulpy consistency, and has numerous gas-bubbles over the surface. It coagulates milk with acid reaction and with evolution of gas. Bacterium lactis aërogenes resembles the lactic-acid bacillus of Hüppe and in many respects the pneumococcus, but is not identical with either.

Pathogenic Properties.—Bacterium lactis aërogenes has no effect when injected subcutaneously into mice. Injected into the blood of guinea-pigs death resulted in twenty-four hours, with symptoms of collapse, and revealing in autopsies the phenomena of intestinal catarrh. Similar effect was produced by the subcutaneous injection of a large quantity, but no effect from a small quantity. The same results are observed in rabbits, save that the action is slower and generally accompanied by diarrhœa. The rapidity of the pathological effects points to a toxic rather than a direct action upon the walls of the intestine.

Bacterium Coli Commune.—This appears to be one of the most widely distributed of all known bacteria. It is found in the meconium, in the fæces of milk, flesh, mixed diet, and in diarrhœa, and appears to be seldom, if ever, entirely absent from the fæces. Bacterium coli commune is considered by Weisner identical with the Naples bacillus of Emmerich. Sternberg[1] found it constantly and as the predominating form in the intestine and often in the stomach in yellow-fever cases.

Bacterium coli commune is characterized not only by its wide distribution, but also by the great variation in the character of its growth and morphology. The latter varies in different stages of growth and in different media. The smaller forms show very little difference in length and breadth, which is about one-half micro-millimetre, while in gelatin cultures some forms reach five micro-millimetres or more in length: all grades between these are seen. In the fæces they are often observed with uncolored places in the length of the rod, giving a pretty spotted appearance. The morphology, which is so variable in the fæces of different children as to require the culture test to recognize it as the same bacillus, is more uniform in the fæces of the same child, and especially in the same stool. This difference is probably due to the slight nutritive alterations in the intestinal contents of different children and in the same child at different times.

---

[1] Further Researches in the Etiology of Yellow Fever, Trans. Assoc. Amer. Phys., 1888.

Bacterium coli commune grows readily upon the ordinary culture-media. On gelatin the colonies are so variable that no characteristic description can be given: they generally spread extensively over the surface and have a bluish-white appearance to the naked eye. Slightly magnified, they are at first white, with fine markings, but as they grow older are brownish or straw-colored. Sternberg has recently found that when twenty-per-cent. gelatin cultures are kept at a certain temperature offshoots appear on the sides of the stalk in the depth of the gelatin. Cultures from the offshoots and from the main stem between them gave different results, the cultures from the offshoots resembling Emmerich's Naples bacillus, those from the main stem the bacterium coli commune. Further cultivation from these low apparently different varieties again gave similar culture-results, which led Sternberg to regard Emmerich's bacillus as a sport of the bacterium coli commune. If this result is confirmed by thorough tests it will explain many of the difficulties experienced by all who have attempted to study the colon bacteria. On potato cultures the bacterium coli commune is more uniform, having a brownish-yellow color, with sometimes a glistening surface. It coagulates milk more slowly than the bacterium lactis aërogenes, requiring from six to eight days at from 30° to 35° C. The pathogenic properties are similar to those of the bacterium lactis aërogenes.

Relation of the Intestinal Bacteria to the Fermentative Processes in the Intestines of Sucklings.—The growth and development of bacteria in the intestinal canal, which contains no free oxygen, or only a slight and insufficient quantity, is dependent upon the presence of some fermentative substance which is decomposed by the activity of the bacteria. Free oxygen, being necessary to the life of all bacteria, can be supplied in the presence of active fermentation (Naegeli). Escherich proved experimentally that milk-sugar supplied the fermentative substance in the healthy intestine of sucklings, it being the only ingredient of milk decomposed by the bacteria found in the normal intestine of sucklings on the exclusion of oxygen, casein and fats being not at all or only slightly acted upon. Of the bacteria found in the normal intestine of sucklings the bacterium lactis aërogenes is the only species which causes fermentation in milk without oxygen, producing a fermentation of milk-sugar with the formation of lactic acid and the development of carbonic acid and hydrogen. According to more recent experiments by Baginsky,[1] it is an acetic-acid and not a lactic-acid fermentation. Baginsky found that the bacterium lactis aërogenes ferments milk-sugar, with the formation of only a minimum quantity of lactic acid and with simultaneous entrance of aceton; that the greater quantity of formed acid is acetic acid; that the fermentation proceeds as well without as with oxygen and is not hindered by the presence of bile-ingredients. The gases accompanying the acetic-acid fermentation are carbonic acid, methan, and hydrogen. There is every reason to believe that it is the bacterium lactis aërogenes which causes this species of fermentation, proved to occur normally in the infant's intestine, and that the intestinal gases carbonic acid, methan, and hydrogen are derived from this fermentation.

Bacterium lactis aërogenes has not been found in the meconium, nor in the intestine or fæces after a flesh diet, but it is always found in the intestine after a milk diet. Its vital activity in the intestine appears to depend upon the presence of milk-sugar, and its extension there corresponds with that of this substance. Milk-sugar is completely absorbed in the stomach and small intestine, and is not found normally in the large intestine. At the time of milk digestion the bacterium lactis aërogenes is found in great quantity in the upper part of the small intestine, and in proportion to the absorption of milk-sugar it becomes scarce, diminishing in number throughout the colon, and in the fæces comparatively few individuals of this species are found.

On the other hand, the bacterium coli commune is found but sparsely in the upper part of the intestine, becomes more and more numerous towards the end of the intestine, and vastly exceeds in number all other species of bacteria in the fæces, being also found in the fæces after a flesh or mixed diet and in the meconium before any food is swallowed. As sugar and casein are absorbed before reaching the large intestine, and the fats but slightly broken up into glycerin and fatty acids, the former being readily absorbed, it seems that no ingredient of milk is of influence in the development of the colon bacterium in the intestinal canal, but rather that some fermentative substance contained in the intestinal secretions is the cause. According to Landwehr,[2] almost the whole of the mucus in the intestine is decomposed, and it is probable that the bacterium coli commune causes some species of fermentation or decomposition of the mucus.

There appear, then, to be two fermentative processes taking place in the intestine after an exclusive milk diet, which are separated both locally and at the time of occurrence. In the upper part of the intestine is a decomposition of milk-sugar by the bacterium lactis aërogenes, and in the lower part a fermentation of the intestinal secretion by the bacterium coli commune. The saccharine fermentation commences with the entrance of the milk ingredients into the duodenum, and, as the absorption of milk-sugar is rapid, it continues but a short time after gastric digestion is completed. The zone of this fermentation is confined to the upper part of the small intestine, and extends with decreasing intensity, according to the stage of digestion and the activity of absorption, more or less down the intestine, without at any time passing the ileo-cæcal valve. The other fermentation begins with the conclusion of the first, and continues until the fæcal mass is thrown off. This slower fermentation of the bacterium coli commune is limited mostly to the large intestine.

[2] Zeitschr. f. Physiolog. Chemie, 1885, Bd. ix.

Participation of Bacteria in the Normal Digestion of Sucklings.—The question as to the extent to which bacteria affect digestion, and whether favorably or injuriously, has not yet received the attention that its importance deserves. Some text-books on physiology ascribe to bacteria an important *rôle*, and consider normal digestion without them impossible; others look upon them as having no physiological importance. In milk digestion, casein, the most important ingredient, appears, according to the experiments of Tiedman and Gmelin, to be completely dissolved and chiefly absorbed in the stomach. Frerichs gives a similar opinion. In puppies and kittens he did not see in a single case undissolved casein below the pylorus.

Among later authors, Reichmann[1] observed a complete change of the originally coagulated casein into the soluble form in the stomach; but it is doubtful if the same occurs in the suckling, where the anatomical nature of the stomach indicates that the food remains but a short time and the gastric juice is less abundant than in the adult. If we consider the action of bacteria upon the ingredients of milk, we find that the albuminous bacillus of Bienstock has no action upon casein and alkali albumen. Of the intestinal bacteria of the healthy suckling, two of the inconstant varieties, bacillus subtilis and streptococcus coli gracilis, decompose casein, but only in the presence of free oxygen. The other varieties have no action upon casein.

An important question has been raised by Uffelmann,—*i.e.*, Are the proteids absorbed or used for the development of bacteria? The number of bacteria in the upper part of the intestine is less than in the lower, and they increase rapidly below the ileo-cæcal valve. Casein and sugar, on the contrary, are continually decreasing through absorption, and do not reach the large intestine, the chief seat of bacterial development. The two constant varieties of bacteria have but slight need of nitrogen, and this is probably derived from the serum albumen for the bacterium lactis aërogenes, and from the secretions of the colon for the bacterium coli commune. The small number of the bacteria in the small intestine indicates but slight need of nitrogen there. It seems probable, as Wegscheider suggests, that the casein of human milk is completely absorbed.

The quick absorption of casein, and the want of albuminous decomposition generally in the intestinal canal of sucklings, which does not appear possible in the lack of proteolytic activity of the milk-fæces bacteria, afford the best explanation for the absence of products of albuminous decomposition and of the fæcal odor from the fæces of sucklings.

[1] Zeitschr. f. Klin. Med., 1885.

Potential or Inconstant Milk-Fæces Bacteria.—Under this head are embraced all those bacteria which do not possess a fermentative action upon any of the materials in the contents of the normal intestine of the sucklings. They are found only in small number, inconstantly, and without perceptible relation to the chemical composition of the nourishment in the normal fæces. They are for the most part aërobic, and, so far as they develop at all in the intestinal canal, probably grow on the peripheral layer, which contains a small amount of oxygen. Corresponding to the greater extension of this layer in the large intestine, they are found there more frequently and in larger quantity, while in the small intestine they appear to be almost completely absent. In sucklings who have suffered from digestive disturbance and whose stools have again become normal, they are found in larger quantity. The inconstant bacteria are, as a rule, somewhat more numerous in the fæces of infants fed with cow's milk than in the stools of sucklings.

Escherich isolated twelve varieties of inconstant milk-fæces bacteria, of which the micrococci were as numerous as the bacilli, and the varieties that liquefy gelatin as numerous as the non-liquefying varieties.

Two facts of the greatest importance are brought to light by Escherich's investigations,—viz., the remarkable and unexpected simplicity and uniformity of the bacterial vegetation in the healthy fæces of milk-fed infants, and the variation in this vegetation which occurs with a change in the quality of the diet.

At first glance it is not easy to understand why, of the manifold varieties of bacteria that gain access to the infant's intestine, only two should develop there constantly and in large number; but this difficulty is lessened when we consider that an organism in order to supply itself with the necessary oxygen and food in the intestine must be capable of causing anaërobic fermentation in the intestinal contents. In harmony with the simple and uniform food of milk-fed infants, we find a corresponding uniformity in their intestinal bacteria.

It is not possible to foresee to what clinical and therapeutic uses the knowledge of the constant characters of the bacterial vegetation in the normal milk fæces may be put. It seems a justifiable inference that any marked variation in the quality of this bacterial vegetation is an expression of some disturbance in the alimentary canal.

Bacteria found in the Dejecta of Infants affected with Summer Diarrhœa.—As long as the normal fæces were believed to contain a chaotic mass of all sorts of bacteria, it seemed a useless and unpromising task to make an especial study of the likewise chaotic mass of bacteria in the diarrhœal stools. This point of view, however, is now changed. With definite information concerning the more important and constant bacterial species in the normal stools, it has become a matter of the utmost interest to learn what new species of bacteria appear in diarrhœal stools and what changes occur in the normal bacterial vegetation.

Such knowledge may prove valuable in many ways. Hitherto the study of the fæcal bacteria in pathological cases has had especially for its object the discovery of some specific forms which might be regarded as the essential cause of disease. This is, of course, a most important object of research.

There is also another point of view hardly less important, which is based upon the fact that the kinds of bacteria found in the fæces vary with the intestinal contents which serve as food for the bacteria. Thus, we find a sharply-defined difference in the bacterial vegetations characterizing milk fæces, meconium, meat fæces, fæces from a mixed diet, etc. In cases of summer diarrhœa there are abnormal changes in the contents of the stomach and of the intestine, in consequence of morbid secretions, peristalsis, and fermentations, and corresponding to these abnormal intestinal contents we may expect to find abnormal vegetations of bacteria, and it is reasonable to suppose that some definite relations may be discovered between certain forms of bacteria and certain definite changes in the intestinal contents. Such a discovery might be of diagnostic and perhaps even of therapeutic value.

It is evident that great caution must be used in assuming that any causal relation exists between strange forms of bacteria in the fæces and the existing disease. Various interpretations of such a coincidence are possible. First, it may be that the new forms of bacteria are to be regarded simply as the necessary accompaniment of the altered intestinal contents, not influencing in any way the disease. Even upon this supposition of their harmless saprophytic nature the study of these bacteria may prove of diagnostic and therapeutic value. In the second place, the new forms of bacteria, while not the primary cause of disease, may by their presence and growth in the intestine cause a continuance and aggravation of the disease. For instance, we can readily suppose that a gastric or intestinal catarrh, or some abnormality in peristalsis or secretion, induced primarily by error in diet, or by heat, or by some constitutional cause, or by unhygienic surroundings, may be kept up and aggravated by the presence of micro-organisms, whose continued existence in the intestine is first rendered possible by some abnormality which would be otherwise transitory. In the third place, the bacteria may begin their work outside of the body, by developing in the milk or other food taken by the infant, and causing abnormal products of fermentation or decomposition, possibly poisonous ptomaines. In the fourth place, one or more of the species of bacteria found in the stools of infants affected with summer diarrhœa, and not found in the normal stools, may be the essential and specific cause of the disease, in the same sense that the typhoid bacillus causes typhoid fever or the anthrax bacillus causes anthrax. It must be admitted that without further proof of any given case the presumption is against this last supposition.

In view of the very peculiar qualities which bacteria must possess in order to adapt themselves to the conditions of growth in the healthy infant's intestine, and the preoccupation of the field by other bacteria, it is not likely that bacteria which enter the normal intestine will be able to displace those normally existing there. That preparation of the soil which we vaguely call predisposition doubtless plays a most important *rôle* in the summer diarrhœa of children. Given a favorable soil, such as that resulting from gastric or intestinal catarrh, or from abnormalities in peristalsis or secretion, bacteria which would fail to gain lodgement in the healthy intestine may grow and by their presence become the most serious factor in the disease.

The only way to attack, with any hope of success, the problem as to the significance of micro-organisms in the diarrhœal stools of children, is to isolate, as far as possible, the various species, according to the modern bacteriological methods, which we owe to Koch. The organisms thus isolated must be studied morphologically and biologically, more especially with reference to their fermentative and pathogenic properties, and, as the different varieties of bacteria may affect the activity of one another, it will be necessary to observe their action when different varieties are mixed. Furthermore, such organisms must be compared with those found in the healthy stools, and the frequency of their presence in diarrhœal stools, and their relation to different varieties of the summer diarrhœa of children, must, if possible, be established.

Our knowledge of the bacteria in the diarrhœal fæces is not so advanced as that in regard to the healthy milk-fæces bacteria, and in the following account of what has been accomplished in this direction it is only intended to give the present state of our information upon the subject, which is by no means sufficiently matured to admit of positive conclusions.

Hayem and Lesage[1] attach great importance to a bacillus which they have separated from the intestinal contents and stools of infants affected with "green diarrhœa." They distinguish two forms of green diarrhœa, the bilious and the infectious. In the former the green color is dependent upon a redundant secretion of bile and upon the presence of an abnormal quantity of bile-coloring matter in the stools. This form appears ordinarily between the fourth and the twenty-fifth day, and is without other phenomena of disease.

The infectious form is essentially different, the stools containing only a small quantity of bile-ingredients and having a neutral or an acid reaction. The green color of the stools in this form is dependent upon the presence of coloring-matter which is produced by the bacillus which is found in the intestinal canal and stools of children affected with this form of diarrhœa.

---

[1] Lesage, De la Diarrhée verte des Enfants du premier Age, Bulletin Médical, 1887, xxvi. 10.

The bacillus is a narrow rod, with rounded ends, from two to three micro-millimetres long and one micro-millimetre wide; in old cultures or under conditions unfavorable to its development it grows in long threads (twenty micro-millimetres). It grows by division and spore-formation, and does not liquefy gelatin. This bacillus is especially found in the upper two-thirds of the small intestine, more sparsely and in long threads in the large intestine and stools.

The most conspicuous property of the bacillus is the power to produce a green coloring-matter which is soluble in water, and which increases to a still darker green when exposed to air. The coloring-matter is produced in cultures on the different nutritive media. In animal experiments with this bacillus hypodermic injections gave negative results. Injected into the blood the bacillus appeared in the duodenum in from ten to twelve hours, and caused, by its increase in the intestine, the green diarrhœa. Similar results followed the injection of the bacillus directly into the intestine, or when it was introduced through the food into the stomach. The experiments were successful only with suckling animals. The bacillus is not found in water or milk, but spreads through the air from drying diapers. The epidemics of diarrhœa in St. Anthony's Hospital date, each time, with the entrance of a patient affected with green diarrhœa, independent of the time of year, and attacked both breast-fed and artificially-fed children.

Baginsky[1] has separated from the dejecta of infants affected with "acid diarrhœa" two varieties of bacteria which liquefy gelatin, one of which produces a green coloring-matter, and he considers this identical with the bacillus described by Hayem and Lesage. As the latter does not liquefy gelatin, it should be regarded as a different variety. The other bacterium described by Baginsky is non-chromogenic, and was found constantly in the diarrhœal stools. This variety is quickly fatal to animals, and Baginsky thinks it probably plays an important *rôle* in the pathogenesis of diarrhœa.

If this bacillus and the bacterium lactis aërogenes, the constant bacterium of the healthy small intestine of sucklings, are introduced at the same time into gelatin supplied with milk-sugar, the bacterium lactis aërogenes shows an active development, with evolution of gas, while the white liquefying bacillus ordinarily does not develop and but exceptionally causes a liquefaction in the gelatin. This led Baginsky to the opinion that the bacterium lactis aërogenes placed under favorable conditions may prevent the growth of pathogenic organisms, and that in the acetic-acid fermentation of milk-sugar caused by the bacterium lactis aërogenes we have a remedy which serves in the infant's organism to protect the intestinal wall from pathogenic bacteria. But when this fermentation exceeds a certain degree, which may happen in abnormal conditions of the intestine, it destroys the bacterium lactis aërogenes and thus lays the foundation for pathological processes of various kinds.

---

[1] Deutsche Med. Wochenschrift, 1888.

In a systematic isolation and study of the biological characters of the bacteria found in the dejecta of infants affected with summer diarrhœa, carried on in the pathological laboratory of the Johns Hopkins University,[1] I have isolated forty varieties of bacteria from the dejecta of thirty infants, eleven of whom had cholera infantum, fourteen catarrhal enteritis, and five dysentery. These children were all seriously sick, especially the cases of cholera infantum and dysentery.

The bacteria found in these cases presented many points of difference from the bacteria in the healthy milk fæces of infants. Not only was a greater variety of bacteria found in individual cases, but most of the cases contained one or more varieties not found in others.

This great variation of the bacterial vegetation in the diarrhœal fæces affords some estimate of the time and labor required for a proper understanding of them, and still more of the great importance of avoiding hasty conclusions in regard to their significance. It seems an endless task to isolate and study all the varieties of bacteria contained in the diarrhœal fæces that can be cultivated even with our present nutritive media.

The greatest number of varieties of bacteria were found in the cases of cholera infantum; a larger number in catarrhal enteritis than in dysentery; and the smallest number in the healthy child used for control, only one variety being found there; but the actual number of individual bacteria in the healthy milk fæces is as great as in that of the diarrhœal fæces.

Eight varieties of bacteria, the largest number isolated in any single case, were found in each of four cases.

The difference in the number of varieties of bacteria found in the fæces does not necessarily indicate a similar difference in the intestinal canal. In the diarrhœal fæces which come from the upper as well as the lower intestine and are discharged at such short intervals that no considerable delay can occur in any part of the canal, the conditions are more favorable for obtaining representations from all portions of the canal than is the case in the dysenteric discharges, which come chiefly from the lower intestine, and in the healthy fæces, which are voided once in twenty-four hours and are probably retained in the colon sufficiently long to cause the death of many bacteria which cannot exist for a long time in the large intestine.

Nor is it claimed that the cultures obtained represent absolutely all the varieties of bacteria contained in the fæces, as the bacteria may not be equally distributed through the fæces, and their colony growth, especially upon agar, to which we are limited in this climate during the greater portion of the summer for plate-cultures, is not always distinctive enough to be recognized. Moreover, not all the bacteria present in the fæces will grow in our ordinary culture-media.

The bacteria in the diarrhœal fæces differ from the inconstant varieties found by Escherich in the healthy milk fæces. In the latter varieties of micrococci are as numerous as those of bacilli, and the liquefying as numerous as the non-liquefying varieties. Chromogenic bacteria also occur frequently. Of the forty varieties of bacteria isolated from the diarrhœal fæces only one was a micrococcus, seven were liquefying, and none were chromogenic bacteria. Culture test failed to identify any variety with the inconstant bacteria found by Escherich.

---

[1] A Study of some of the Bacteria found in the Dejecta of Infants affected with Summer Diarrhœa, Trans. Ninth International Med. Congress, vol. iii., 1887.

The constant or obligatory bacteria of the healthy milk fæces do not disappear in the diarrhœal fæces.

The bacterium coli commune, or varieties of the colon group of bacteria, were found in all cases of diarrhœa, but not in the largely predominating form as is the case in the healthy milk fæces, and appeared to diminish in number according to the severity of the disease. They were not found in the dysenteric discharges.

The bacterium lactis aërogenes appears more frequently and in larger number in the diarrhœal than in the healthy milk fæces, and was found in most but not in all of the cases.

No variety of bacteria has been found which bears the relation cf constant or obligatory bacterium to the diarrhœal and dysenteric discharges which the colon bacterium bears to the healthy milk fæces. Many of the varieties of bacteria were found only once, while others were discovered in two or more cases, but no variety was found in a sufficiently large number of cases to be of importance from that fact alone.

Bacteria belonging to the proteus group were the most frequent, and were limited to the more serious cases of cholera infantum. Varieties of this group were found in seven of the eleven cases of cholera infantum, proteus vulgaris in three cases, and a variety, which I have designated bacillus A, in four cases.

Bacillus A produces the swimming colonies in gelatin, but differs from proteus vulgaris in coagulating milk with alkaline reaction, in the growth on potato, and in having a nearly uniform morphology. It is a narrow bacillus, with rounded ends, varying in length, but with an average size in fresh cultures of three micro-millimetres long and seven-tenths of a micro-millimetre wide. The bacillus is motile, liquefies gelatin, and renders slightly-acid milk alkaline, producing a gelatinous coagulation with alkaline reaction. It grows readily in agar; in stab cultures the surface is covered in a few days with a nearly colorless scum, and in the depth is a delicate and luxuriant stalk corresponding with the line of insertion of the platinum needle. Agar colonies are round and bluish white and often diffused through the agar; slightly magnified, the colonies are light brown, with indistinct borders.

The presence of members of the proteus group of bacteria in a large proportion of the most serious cases having symptoms of cholera infantum, as collapse, stupor, vomiting, and frequent watery and offensive stools, is not without significance.

Escherich found the proteus vulgaris in the meconium, but he did not find any of this group in the healthy milk fæces. In the healthy suckling the albuminous ingredients of milk are probably soon absorbed and remain but a short time in the intestine.

According to Hauser, the proteus group of bacteria do not grow in the so-called normal solution, and seem to require highly-organized, especially albuminous, compounds. They excite putrefaction in animal tissues, with the development of a serious poison and evolution of stinking gas, and, on account of their wide distribution and frequent occurrence, belong to the most important and common putrefaction-exciters.

Pathogenic properties, as manifested in experiments upon the lower animals, appeared very marked in this group of bacteria. Milk cultures of bacillus A fed to mice and guinea-pigs resulted fatally in every case, death occurring in from one to eight days. Autopsies revealed nothing abnormal except a certain degree of emaciation. The bacillus was found by the culture-test in the stomach and intestine of all the animals, and, as a rule, in greater number in the small than in the large intestine. It was also found in some cases in other organs, especially the kidney. In all the animals to which the milk cultures were fed more or less stupor was produced.

Bouillon cultures of bacillus A eighteen days old, when sterilized by the interrupted method, and injected in small quantity (one-half cubic centimetre) into the jugular vein of rats, resulted in death in from two and a half to five hours. A small quantity of an eight-days' agar culture put into one cubic centimetre of sterilized water and one-half of this injected into the jugular vein of rats was without results. From this it appears that the pathogenic properties of bacillus A reside in its power of producing injurious products in albuminous compounds.

Diarrhœa was not a prominent symptom in the animals in which experiments were made, a pronounced diarrhœa being observed in only one case.

Bouillon or liquefied gelatin cultures, two weeks old, of a bacillus apparently identical with proteus vulgaris, injected into the ear-vein of rabbits, resulted in death in from two to twenty hours. Active diarrhœa occurred a few hours after the injection in a number of the rabbits, but not in all of them. Drowsiness and accelerated breathing were prominent symptoms in all cases, and in some the drowsiness was preceded by restlessness. Similar cultures injected into the intestine after the abdomen had been opened in a bath of normal salt solution at 38° C., Sanders-Ezn's method, caused active rhythmic and peristaltic contractions.

Another bacillus having marked pathogenic properties in lower animals was found in four very serious cases of cholera infantum. It is a small bacillus, with rounded ends, from one to two micro-millimetres long and one-half micro-millimetre wide, and liquefies gelatin rapidly. Stab cultures are liquefied along the line of insertion of the platinum needle, trumpet shape; the liquefied colonies are uniformly granular. It grows luxuriantly on potato with a light-yellow color when fresh and a slight pink tint as the culture grows older. Bouillon cultures of this bacillus injected into the ear-vein of rabbits resulted in death, and injected into the intestine by Sanders-Ezn's method caused rhythmic and peristaltic contractions.

The other varieties of bacteria with which experiments were made on lower animals did not show any decided pathogenic properties.

The bacteria isolated from the diarrhœal fæces do not multiply in ordinary hydrant-water, and retain an active developmental condition but a short time after being placed in it. Water inoculated with the different varieties failed to give cultures in any case after forty-eight hours, and in a great number of cases after twenty-four hours.

All the varieties thrive and many produce important changes in milk. Some cause coagulation with acid reaction, some render it acid without coagulation, some alkaline without coagulation, and others change slightly-acid milk into alkaline and then coagulate it with alkaline reaction. Some cause milk to become a transparent fluid without coagulating it, while others produce this change after first coagulating the milk. Seven varieties in addition to the bacillus lactis aërogenes produce active fermentation in milk, but the nature of the fermentation has not yet been ascertained.

Milk undergoes a considerable change in microscopical appearance in a short time when inoculated with certain varieties of bacteria, while with others no change is perceptible for weeks.

Fresh milk examined under the microscope shows only oil-globules floating in a colorless fluid. When sterilized, kept for weeks, and then examined, no difference is observed beyond a greater tendency of the oil-globules to run together, and in very old specimens a few crystals or fatty acids.

Fresh sterilized milk inoculated with bacterium lactis aërogenes and kept in the thermostat forty-eight hours shows under the microscope a considerable quantity of fine granular matter of yellowish-brown appearance, and at the same time a diminution in the quantity of oil-globules: four to six days later little is to be seen but this granular matter and the bacteria, only a few oil-globules being present. If a small quantity of bile is added to the milk no difference is observed from the pure milk cultures, but the addition of a large quantity of bile requires a longer time for the disappearance of oil-globules and the deposit of granular matter. This granular matter, probably the casein of milk, is dissolved by caustic potash, and is not colored black with osmic acid. Several other varieties have a similar effect upon the microscopical appearance of milk, and in one variety the changes appear to be hastened by the addition of bile. With other varieties little if any difference is observed even after a considerable time has elapsed.

Bile is not destructive to the bacteria found in the diarrhœal fæces. Most of the varieties of bacteria isolated were introduced into pure bile taken with aseptic precautions from the gall-bladders of freshly-killed dogs, and from this cultures of each variety were obtained after the bile had remained several days in the thermostat.

The yellow color given to milk when bile is added is affected differently by the different varieties of bacteria. Bacterium lactis aërogenes gives a bright yellow color to the mixture. Some varieties reduce the bile coloring, giving a whitish-gray or white color to the mixture. Some give a brown color, and others show no difference from the control.

As far as the biological characters of the bacteria in the diarrhœal stools of infants have been studied, it appears that not one specific kind but many different kinds of bacteria are concerned, and their action is manifested more in the alteration of the food and intestinal contents, and in the production of injurious products, than in a direct irritation upon the intestinal wall.

ACUTE AND CHRONIC CONSTIPATION.

By CHARLES WARRINGTON EARLE, M.D.

Definition.—A delayed expulsion of fæcal matter, a retention of intestinal excrementitious substances beyond the normal period, infrequent or incomplete alvine discharges, or a scarcity or complete absence of fæcal evacuations. Constipation is only a relative term, and, according to some authorities, should not be confounded with costiveness, which is merely scanty fæces. It is frequently a part of the phenomena of disease, and while in many cases it produces pathological lesions, in other cases it even does not give rise to any morbid conditions, but is present in those who enjoy a comfortable degree of health. It has been suggested that those having a tendency to constipation are more apt to contract, from accidental or slight causes, a habit which is attended with pathological results.

Constipation, then, is not so much a disease in itself as it is a symptom of various morbid conditions. It is, therefore, exceedingly difficult to define this condition in children; for oftentimes it is merely a trivial affair, while at other times it not only is serious, profoundly affecting the patient at once, and remotely other organs and the general nutrition of the entire body, but jeopardizes life itself.

History.—The inconveniences and danger of the constipated habit were recognized by the early authors. Hippocrates pointed out many of the pathological results produced by the difficulty we are considering, and as means of relief suggested laxatives, injections, and suppositories. Celsus and others also mentioned the subject. Very little, however, has thus far been written regarding the constipation of children. In some of the most exhaustive works on pediatrics published ten and twenty years ago, hardly a paragraph is devoted to the subject. This is true respecting the works of our eminent countrymen Prof. J. Lewis Smith and Drs. Meigs and Pepper, although in Prof. Smith's last edition, 1886, we find probably the most valuable article on the subject in the English language. It is true also concerning the great work "Maladies des Enfants," by the French authorities Barthez and Rilliet (ed. 1861), and even in German literature on sick children the subject is hardly mentioned. In Gerhardt's Handbook we do find an article of eleven pages by Widerhofer, but in the *Archiv für Kinder-*

heilkunde, the publication of which was commenced in 1880, not a single complete article has appeared.

There are certain anatomical, physiological, and dietetic reasons for constipation in children that do not exist in the adult.

Anatomy.—The small intestine is relatively longer and its calibre smaller in the child than in the adult. The walls are also thinner and weaker. The ascending and the transverse colon are shorter compared with the adult, and the descending portion is longer. A larger number of curves and, possibly, angles are formed, because of pressure from above by the liver, which is larger in the child, and of the contracted condition of the pelvis, which is well known to be smaller than in the adult. These anatomical peculiarities give less space to the intestinal tract, and in some cases really represent an etiological factor in causing constipation. The peristaltic movements in babies are slight, because of the imperfectly-developed muscular structure. As a child develops, both peristaltic and muscular tones are increased. Another anatomical peculiarity in the lower bowel which induces constipation in children is the deep cul-de-sac which the sigmoid flexure forms before it enters the rectum. This peculiarity predisposes to fæcal accumulations. One authority, Gerhardt, says, however, that the sigmoid flexure does not make the deep and great anterior and backward curves which have been represented by some authors.

According to Jacobi, the length of the intestinal tract in children, with its tendency to overlap and elongate, is a cause not only of constipation, but also of the more serious surgical difficulties, such as intussusception, etc. Treves has recently pointed out the anatomical changes in the colon that almost always attend chronic constipation.

Physiology.—In a healthy child the mother's milk is mostly absorbed and assimilated, leaving but a small residue, and the amount of material evacuated has some relation to the amount taken into the system. The albumen of milk is nearly all digested in the stomach and bowels of the child, and from this very process we have a physiological cause of constipation in children,—fæcal matter existing in such small amount that intestinal peristalsis is not excited. In older children and adults, if constipation has not become habitual, the rectum is usually empty. When defecation is regular, the fæcal mass descends into the rectum and produces the uneasy sensations which precede a healthy evacuation. If this call is not heeded, a reverse peristalsis is excited in the walls of the rectum, and the fæcal matter is returned to the sigmoid flexure. If this neglect becomes habitual, the return to the upper bowel does not take place, and an accumulation follows, with all its attendant evils to pelvic circulation.

In infants, on account of the pasty condition of the intestinal matter, it seems normal for the rectum to contain more or less excrementitious material, which explains in some degree the number of daily evacuations from the bowels which must be regarded as natural in the infant or child.

What, then, constitutes constipation in an infant? This is a difficult question to answer, and it appears to me that only by observing the character of the passages and noting the growth of the child can we intelligently decide. One evacuation each day, in a small number of cases, may be sufficient, but frequently where this is the habit some of the deleterious results of constipation will be noticed. On the other hand, we have frequently noted from three to four movements each day, and have found, by actual weight of the child, a normal increase from week to week, with every other indication of good development. From one to four passages each day, then, would be regarded as normal. Deviations from the normal, such as an evacuation every time a napkin is changed during the first year of infant life, to a passage once in seven or eight days, and, in the older literature, a single passage once in several months or even in a year, have been noted. A gradual increase in weight and a general good condition of nutrition must be our guide in deciding this question.

Constipation is undoubtedly more frequent in adults than in children, but the habit, with all its attendant evils, is more frequent in children than one would suppose from the meagre literature on the subject. Exactly where, in children, constipation commences to be pathological is a difficult point to decide.

After considerable study, I have come to the following conclusions in regard to what should be considered normal evacuation of the bowels in infants and children. In infants it is perfectly natural for at least three or four evacuations of the bowels to take place daily ; and, viewed from this standard, a nursing child having only a single passage each day would be in an abnormal condition. Between the first and the second year it is normal for two movements to take place daily. At the beginning of the second year, usually both movements from the bowels and the bladder become voluntary ; yet occasionally we find children within the first year who regulate very fairly these functions, and later on in a child's life we find them taking on family peculiarities. In all probability, what we call family peculiarities or hereditary tendencies are due more to neglect of the proper attention to the wants or habits of children, or to the perpetuation of a family habit of continually giving and taking purgatives. In every case it is necessary not only to inquire as regards this family peculiarity, but also to consider the character as well as the frequency of the intestinal discharges.

Frequency.—Nearly all children suffer in some degree from constipation. It is "an unpleasant and not rare occurrence." Some authorities state that it is one of the commonest disorders of early life. In many cases it is only a transient difficulty, while in others it is a malady which will follow its little victim through the entire period of childhood, affecting not only its present health and comfort, but also its future development.

Interference with normal peristalsis, which may come from many causes, will produce most remarkable variations in the normal evacuations as well as in the nutrition of the child.

Quantity of Fæces.—According to Bouchard, a baby passes about two and a half ounces of fæcal matter daily. This, in proportion to its weight, is much more than is evacuated by the adult. In the middle part of childhood the intestinal passages become more like those of the adult, although much depends upon the diet. A larger amount of food relatively is taken by a child than by an adult. It is not retained in the bowels as long as in the adult; consequently less time is given for its absorption. It is a well-known fact that while the food is in the stomach and intestinal tract of a child absorption is rapid, and the fæces of children suffering from constipation are almost always dried or changed in a very remarkable manner.

Etiology.—In the first place we will consider more particularly the causes of constipation in infants at the breast, then in older children.

Besides the anatomical and physiological peculiarities which I have already enumerated, and the mechanical obstructions and congenital malformations mentioned elsewhere, there are many causes, more particularly relating to the diet of children, which produce constipation. First, a constipated habit on the part of the mother frequently has to do with the constipation of the child. The mother's milk sometimes contains too much casein, or too little sugar, and in other cases is so thoroughly digested that but little residue remains and constipation ensues.

A sluggish condition of the muscular coat of the intestine, a diminution in the secretions either from the mucous membrane or from the glandular apparatus, and improper food are other causes, to which may be added the imperfect muscular development in feeble and delicate children.

In order that there shall be a free and normal movement of the bowels there should be considerable fæcal matter in the colon: not only must we have automatic peristaltic action, but there should be, it appears to me, the stimulus which comes from an adequate amount of fæcal matter. It is useless, then, to expect a movement of the bowels within several hours following free catharsis.

An inflammatory condition, causing more than the usual amount of œdema, producing a constriction of the circular fibres, may take place and cause constipation. This form of constipation simulates stenosis. To differentiate, one should remember that if vomiting takes place it will not be of the stercoraceous variety.

Artificial foods, including condensed milk, in many instances produce diarrhœa, but in other cases give rise to constipation; and any food which is absorbed quickly, leaving little or no residue, will produce this condition. To obviate this, if water has been used as the diluent, oatmeal-water should be substituted.

In older children a solid food, or vegetables with a large residue, or fruits, such as bananas, with an insufficient amount of liquids, in connection with a condition of the bowels favoring retention, are frequent causes of constipation. Over-stimulation and consequent atony of the bowel, whether from coarse food, frequent purgations, or large enemata, are causes.

Among other articles of food which may produce constipation are rice, arrow-root, boiled milk, and tea. Impaction of the bowel, more particularly in the lower part, may take place from a variety of causes, such as large masses of hardened fæcal matter, fig-pits, and stones from fruits. It is believed that intestinal worms (generally the lumbricoids) will give rise to the condition described.

Deficient intestinal secretion, by producing a hard and pebbly condition of the fæcal mass by the time it reaches the colon and rectum, causes constipation. Where there is a deficiency, particularly in the bile or other secretions, and articles of food which cause fermentation are taken, an enormous accumulation of gas may take place, producing not only constipation but sometimes convulsions.

Excessive perspiration, either in the course of diseases or produced by the action of baths or drugs, may also be a cause of constipation.

All kinds of medicines administered to quiet pain or restlessness, whether prescribed by the physician or given surreptitiously by the nurse, are constipating. The same may be said of many of the tonics which contain astringents, particularly tannin; and one authority speaks of toys containing lead as a possible etiological factor. In this connection I should add the too free use of aperient medicines, producing over-stimulation and subsequent enfeeblement of muscular activity.

All local diseases of the rectum, as fissures and hemorrhoids, producing painful passages, predispose to constipation. The child delays its normal movement from dread of stool on account of pain, and soon there results distention of the lower bowel from accumulation, which, although secondary, produces the malady under consideration.

A neglect to inculcate a habit of regularity in going to the closet, the false modesty which is frequently felt by young girls, the inactivity of indoor life, and a want of exercise, induce constipation. In young girls subject to constipation we almost invariably find anæmia and neuralgia.

Constipation also arises from hernia, intussusception, intestinal obstruction from carcinoma, and congenital malformations of the rectum. It may be caused by chronic peritonitis, by tumors, and, in the female child, by a retroflexed uterus.

We may also include the constipation which occurs in meningitis, in myelitis, in hydrocephalus, and in micro-cephalic children. The bowels are sluggish in diseases of the cerebro-spinal system, due in part to interruptions in the motor nerve-currents or to a state of tonic contraction in the abdominal and intestinal structures.

All kinds of obstructions produce constipation, but, from lack of space, only a few can be here enumerated. Dr. Cheever relates a case of recurrent constipation first noticed a few days after birth. The anus and rectum were found normal, and at this time no abdominal tumor could be detected. The stools were of usual size, showing that the obstruction was above the sigmoid flexure. The trouble was overcome for the time by cathartics, but when the child attained the age of two years he again came under the doctor's observation. The child's appearance was remarkable: the head was small and the lower part of the abdomen large; he was cone-shaped. He was fairly nourished, but from time to time he would suffer from intestinal obstruction, pain, and vomiting. An operation, with restrictions on the part of the parents, was resorted to, with the result of finding a dilatation of the intestines, containing about two quarts of fæcal fluid. One end of the dilated bowel was attached to a piece of contracted and strictured intestine, quite impervious to solids, twelve or eighteen inches long, ending at the sigmoid flexure. This case demonstrates that fluid fæces may come through a constricted portion and assume their normal consistency and shape either in the sigmoid flexure or in the rectum.

Finally, in many of the chronic and wasting diseases, especially those enfeebling the muscular movements having to do with defecation, and, in general, producing a low condition of the system, constipation is present.

As a most valuable contribution to our knowledge of the etiology of constipation, I present a condensed table from L. Martineau's elaborate article on the subject as it relates to children.

A. Constipation from Disturbances in the Contractility or Sensibility of the Intestinal and Abdominal Walls.

I. Constipation from Paralysis of the Intestines.—1. Affections of the intestines.—Constipation may result from either primary or secondary (by extension from the mucous membrane) inflammation of the muscular coat. It is not uncommon to find in children ulcerations of the mucous membrane, which had previously caused diarrhœa, suddenly give rise to considerable abdominal distention and a most obstinate constipation.

2. Affections of the peritoneum.—Paralysis of the intestines from these causes is much more frequent than from the preceding. According to Barthez and Rilliet, in acute peritonitis in children, constipation is the exception and not the rule. Duparcque, on the contrary, asserts that constipation exists in the majority of cases. In chronic tubercular peritonitis, constipation never persists throughout the disease: it alternates with diarrhœa.

3. Affections of the nervous centres.—(*a*) In diseases of the brain and its membranes,—as in tubercular meningitis, where constipation is almost always the rule, and sometimes in acute meningitis; in serous or hemorrhagic meningeal effusions; in softening of the brain; in cerebral congestion or hemorrhage; in tumors of the brain. (*b*) In affections of the cord or its membranes, as spinal meningitis, congestion or hemorrhage, acute and chronic myelitis, and tumors,—which are more often the cause of constipation than are cerebral affections. A most obstinate constipation, due to paralysis of the sphincters of the anus, sometimes marks the onset of locomotor ataxia.

II. Constipation from Paralysis of the Diaphragm or of the Abdominal Muscles.—Neuralgia of these muscles, by preventing their action,—the least motion occasioning pain,—leads to constipation. Hyperæsthesia of the abdominal muscles, so common in the hysterical, would act in like manner; so also would herniæ, which, owing to the risk incurred, prevent patients from exerting sufficient force.

III. Constipation from Reflex Intestinal Paralysis.—This may be the result of (*a*) affections of organs more or less in the vicinity of the intestines,—as a testicle, retained in the inguinal canal, becoming inflamed; (*b*) affections of organs connected with the intestines, as hernia of the vermiform appendix, umbilical hernia, and abscess in the iliac fossa. A proof that constipation resulting from the above causes is reflex is afforded by the fact that the phenomenon of paralysis is preceded, as in all reflex paralyses, by signs of irritation, as pain, vomiting, and abdominal distention. To the above causes may be added (*c*) lack of sensibility in the mucous membrane of the intestines. The result of this is seen in persons who do much brain-work or lead a sedentary life, and who make an abuse of rectal enemata or of certain medicines, as opium, purgatives, etc., which eventually act by diminishing sensibility or producing atony of the mucous membrane. Opium, however, would cause paralysis of the muscular coat. To this loss of sensibility of the mucous membrane must be ascribed the constipation so frequently met with in hysterical girls.

IV. Constipation from Exaggerated Contractility of the Intestines.—Spasm of the intestines becomes an impediment to the passage of its contents. Under the name "spasm of the intestines" Billard has described an affection accompanied with constipation, which affection, according to him, is quite common in new-born babes. Spasm of the sphincters may act in a similar way, and is usually the result of fissures, sometimes of hemorrhoids.

V. Constipation from an Altered State of the Blood.—This cause produces constipation either by its effects on the intestinal secretions or by its direct influence on the nervous system. Thus, in convalescence from acute diseases we may have paralysis of the muscles of the intestines as we have of other muscles. Maingault and others have observed this phenomenon after diphtheria. There occurs in certain cases paralysis of the rectum. Whether this paralysis is due to an altered state of the blood is yet a question.

B. CONSTIPATION FROM DISTURBANCES IN THE GASTRO-INTESTINAL SECRETIONS.

I. Causes interfering with Chymification.—(*a*) Cancer and ulcer of the stomach; (*b*) gastritis, acute or chronic; (*c*) insufficient alimentation and improper food and drink,—frequent causes in children; (*d*) moral causes, physical suffering, vicissitudes of all sorts,—in a word, all causes of dyspepsia.

II. Causes interfering with Chylification.—(*a*) Duodenitis and acute enteritis; (*b*) fevers; (*c*) intestinal dyspepsia; (*d*) hepatitis and cirrhosis of the liver; (*e*) catarrh of the bile-ducts.

C. Constipation from Mechanical Obstruction.

I. From within.—(*a*) Foreign bodies introduced; (*b*) worms,—both these causes are particularly present in children; (*c*) gall-stones; (*d*) polypi; (*e*) large hemorrhoids; (*f*) invagination, volvulus, etc.; (*g*) abnormal flexures; (*h*) diminished calibre of the intestines from hypertrophy of its coats or new growths.

II. From without.—(*a*) Compression of the intestines from enlarged organs or tumors; (*b*) strangulation by bands or in hernial sacs.

Pathology.—This part of our subject has not been well worked out. Indeed, until recently but few articles had been written upon the subject as it relates to children. Many valuable facts have been brought out, but in only a few instances have they been tabulated or made available to the profession. While it must be admitted that constipation may exist in children for years and no alteration of the parts be observed, on the other hand, not only is its existence frequently accountable for the lack of development, but its effects are far-reaching, as is demonstrated by some of the distressing ailments of advanced childhood.

Constipation affects different children differently. The full-blooded and bilious child needs more frequent evacuation than the spare and anæmic one. It seems to be clearly established that the retention of meconium will occasionally produce convulsions. Schlumberger cites cases which demonstrate this beyond any reasonable doubt. In this connection should be mentioned the opinion and clinical observation of Lazarre-Rivière. He believes that constipation comes in the list of reflex causes of eclamptic attacks, and records the case of his grandson, who died of convulsions caused by an obstinate constipation of only a few days' duration.

Since it is impossible to determine definitely when constipation commences to be pathological, the only correct measure will be found in the evil results of imperfect defecation; and this will be seen to differ greatly as we examine different cases. Sometimes we find, as remarked above, absolutely nothing; while in other cases the intestinal mucous membrane presents a simple hyperæmia, or various stages of catarrh or ulceration. We have also called attention to certain anatomical and physiological peculiarities as etiological factors: thus, we observe, when they are present, changes in the position, size, and walls of the intestines. I need not again refer to the displacement of the colon, particularly the transverse, and to the dilated condition of the sigmoid flexure. In chronic constipation the walls of the bowel become thin, and Johnston believes that in long-continued cases a fatty degeneration takes place, which explains to a considerable extent the loss in the contractility and propelling power of the intestines. In infants we find constipation producing repeated attacks of colic, which may disappear without alarming symptoms if speedily relieved, but if long continued bring about a swollen and distended condition of the bowels. The liver may be pushed upward, and in some cases the diaphragm interfered with, so as to cause symptoms referable to the respiratory apparatus.

Prolonged constipation in the young child produces disease in the cæcum,—chronic inflammation, and in some cases induration and thickening. Perforation of the intestine occasionally takes place. Among other serious consequences that sometimes occur are the different forms of hernia, varicocele, prolapse, fissure, catarrh of the bladder, spermatorrhœa, and particularly hemorrhoids.

In addition to the conditions spoken of above and referable particularly to the digestive tract, we have symptoms of pressure on blood-vessels, producing at one time a hemorrhoidal tendency and at another a slight œdematous condition of the feet and ankles. The nerves in the pelvis may also be pressed upon by fæcal masses, and disturbed sensibility—formication, weariness, pain, or weakness in the lower limbs—be the result.

Chronic constipation with accumulation produces not only dyspnœa, but also disturbances in the thoracic circulation. Palpitation, irregularity of the pulse, and vertigo frequently result; and in anæmic girls we find rebellious headaches, hypochondria, and morbid thoughts. The same cause, when present in the lower part of the abdomen, produces in a few cases difficult and frequent micturition.

The relation of constipation to the nervous system, and the influence of the latter on digestion and the general nutrition of the body, are set forth by Martineau as follows. The nervous system and the blood play a very important *rôle* in the process of digestion, since they preside over the secretion of the juices necessary for the metamorphosis of food, and over the contractions of the intestines so essential to intestinal absorption. Let that secretion diminish or stop through changes in the blood or through lesions of the nervous system or of the glands themselves, and elaboration of food will no longer take place, and constipation will be one of the resulting disturbances. Or should peristalsis of the intestines cease, owing to failure of the sympathetic to act, or to its exaggerated action, to altered state of the nervous centres, or to paralysis or enfeeblement of the abdominal muscles that assist peristalsis in expelling the fæces, the act of defecation could not take place, and constipation, with all its attendant evils, would result.

Habits of constipation due to neglect in school-days will frequently follow a patient for years, and have much to do with the production of chlorosis in girlhood. There have been during early growth and early development a poor appetite, poor digestion, and constipation, and, as a consequence, greatly-impaired nutrition, impoverished blood, and a resulting anæmia. Again, where a part of the contents of the bowels is habitually retained, a greater or less fermentative action may be set up and effete and poisonous matter be absorbed, producing those symptoms of indifference and inactivity, want of appetite, etc., which are sometimes noticed in children.

So far as my observations extend, bacteria play little if any part in the production or in the evil effects of constipation. Casein is not changed at all by bacteria; and the same may be said in regard to the fats. Sugar of milk, however, is changed by being split up into the various acids: this takes place in the upper part of the small intestines. The process of decomposition going on in the intestinal canal during the course of a milk diet is to be regarded less as a putrefactive process than as one of fermentation, and the multiplication of bacteria, which we know takes place in the colon, is not at the expense of ingested food, and consequently is of no importance in the consideration of the nutrition of nurslings or of the constipated habit.

Symptoms.—Symptoms are not numerous in acute constipation. In the chronic form they are found in greater numbers, and, except in very rare instances, exercise a much more baneful influence on the immediate health and development of the child.

Occasionally acute constipation will produce a condition which may jeopardize the health, if not the life, of the child; but this is not usual. In the chronic form, as we have pointed out in the section on pathology, serious lesions affecting important organs are frequent.

A single evacuation each day, attended with straining, in a nursling is constipation, which in many cases inclines to become worse until a movement of the bowels can be produced only by medicines or injections. The usual symptoms found in such a case would be the infrequency of evacuation, the slight hardening of the fæces, and the difficulty of their expulsion. All other symptoms might be functional, which would vary according as the case became chronic and the bowels became replete, or as the constipation was caused, as it sometimes is, by complete emptiness of the intestine. One writer has described the constipation of a single day, which is of particular importance in a robust child into whose alimentary canal a proper amount of food is taken. These symptoms are diminished appetite, increased volume and resonance of abdomen, colicky pains, fulness, and a feeling of weight in the lower bowel. If this continues for another day the face is flushed, the head somewhat hot, and the child nervous. In very young children we sometimes notice a pallor of the face, and, rarely, a jaundiced condition of the skin; indeed, a true jaundice sometimes supervenes, from pressure on blood-vessels and consequent obstruction. With symptoms as severe as those just mentioned the general nutrition of the child would suffer, and reflex action, such as convulsions, might ensue. Constipation in children under two years of age sometimes causes symptoms which simulate very severe disease, more particularly referable to the nervous system,—such, for instance, as high fever with slight facial convulsions and grimaces.

In older children the loss of appetite is more marked, the furred tongue (of minor importance in the nursling) is more pronounced, the breath is offensive, and the child has headache and colic and rests badly at night. The complexion loses its clearness, and the child is listless and morose.

Usually, however, in nurslings we find constipation producing only slight colic, some distention of the abdomen, and slight straining at stool. In older children the objective symptoms are more noticeable, and there is loss of appetite, with a coated tongue and bad breath, more or less lassitude and headache, and a feeling of heat in the face and head. The desire to evacuate the bowel is not so frequent nor so pronounced as usual, and where efforts are made only small, hard pieces of fæcal matter are expelled. In these cases there is a feeling of fulness and pressure in the rectum, and sometimes the anal opening is found red and excoriated.

In some forms of constipation there occasionally occurs a peculiar kind of diarrhœa, produced as follows. The hard fæces acting as foreign bodies provoke a more or less abundant fluid secretion, which finds a point of exit either between the fæcal mass and the intestinal wall, or through a lumen dug out of the fæcal accumulation (Racle). Thus an obstinate constipation, with retention of immense masses of excrementitious stuff, may be mistaken for, and treated as, a case of diarrhœa.

In still older children,—those approaching youth,—if constipation has become a habit we find, in addition to the objective symptoms already described, others, which produce disturbances by pressure and have also a depraved influence on nutrition. Along with a distended abdomen, furred tongue, hot mouth, offensive breath, headache, and sometimes vomiting, there is such a degree of abdominal distention that some of the internal viscera are displaced, breathing is difficult, and in girls a condition is present which in after-years may develop a displaced uterus. Pain and uneasiness referred to the bladder are produced, and, from this and other causes, bladder- and kidney-troubles have been suspected when only constipation existed.

In some cases a general cachexia, persistent and significant, is produced, and symptoms referable not only to the alimentary canal but also to the nervous system and general nutrition are most noticeable.

In some children, where constipation has become habitual, there is a change in habits and character. Those fond of work and study can do nothing, on account of a persistent headache, and, while no physical signs of disease can be found, they are morose and melancholy.

The constant bearing down which is present in chronic constipation may produce hernia, hemorrhoids, fissures, and other symptoms referable to the rectum. The presence, too, of fæcal masses for a long time in the rectum may produce follicular disease of the lower bowel, and, in some cases, diphtheritic patches.

In a few cases the colon has become so enormously distended that, with the pain and tenderness, peritonitis has been simulated, and, with an obstruction formed by œdema or from other causes, the colon has appeared to fill nearly the entire abdominal cavity. Indeed, to such an extent have these enlargements attained that a diagnosis of chronic peritonitis and tabes mesenterica has been made.

Stubborn constipation may give rise to fæcal accumulation and symptoms of intussusception. Marmaduke Shields narrates a case in which small motions "like pebbles" were passed; then came incessant vomiting, discharge of blood and mucus from the bowel, and prolapse. Syncope occurred, with profuse sweating, and death seemed imminent. At this time a hard, irregular swelling in the left lumbar region was discovered, and an examination per rectum established the diagnosis of accumulation and impaction. This leads me to say that in making a diagnosis of fæcal tumors we must consider their location, their consistency, and one's ability usually to change their position. We should observe, also, the influence of treatment, particularly of repeated injections. If the tumor is well down in the bowel, we should notice the gradual lessening in size as the small, hard fæcal masses are loosened and brought away by the injections.

Diagnosis.—It should always be remembered that a small amount of fæcal matter evacuated by a child whose alimentation is insufficient as regards quantity should not be regarded as indicating constipation. The presence of this condition will usually not be difficult to establish. In the acute variety there will be infrequency of normal passages from the bowels, pain upon pressure on the abdomen, accumulation of gas, a coated tongue, and a hot mouth.

We should not count as constipation the inability to perform the act of defecation which results from congenital defects or surgical obstructions. These will be treated elsewhere.

In chronic constipation we may be obliged to base a diagnosis more upon the effects previously produced than upon the symptoms actually present. The continued tenesmus or the presence of hemorrhoids or of a hernia will, in many instances, suggest the trouble.

Prognosis.—As regards life, I have always regarded the prognosis as good, although Bouchat believes that in one case constipation caused death; at least no other cause could possibly be assigned. It is in its consequences, both immediate and remote, as causing sickness and improper development, that constipation becomes at times serious and possibly dangerous. This condition, when existing in only a moderate degree, produces slight stomachic disturbances, distention, and tenesmus, and is but a transient or trivial affair. This same condition, however, coming to be more pronounced causes fever and restlessness with its possible sequelæ. Convulsions take place not only from a slight constipation when the irritant is active, but frequently also from the retention of large fæcal masses. In my judgment, a convulsion is always dangerous, by whatever cause produced. A stoppage of the bowel temporarily by food or fruit will nearly always produce restlessness and frequently night-terrors. An extreme nervous condition, bordering on a convulsion, is often noticed in a comparatively healthy child with a nervous temperament, who, suffering from constipation, fears the pain incident to a movement of the bowels. Many of the so-called sick or nervous headaches of children are caused by fæcal absorption, and, while the constipation may be constant, the symptoms of poisoning or the convulsion produced may only be periodical or occasional.

As the child becomes older, if a constipation is neglected or improperly treated, the probabilities of its producing ill effects are increased. In infancy, if the diet is changed and the attention given which the subject demands, a constipation will usually be cured, but if it exists without attempts at its amelioration in older children it is liable to become chronic, influencing the general development, and, in female children, giving rise to uterine displacements.

Prognosis in Chronic Constipation.—As to life, this is also good, but locally it produces diseases of the rectum, hemorrhoids, fissures, and herniæ. In some cases such a degree of stenosis is produced that the most serious results are anticipated, and laparotomies have been performed with the expectation of finding intussusceptions, etc. To avoid such mistakes, which, previous to the days of antiseptics, certainly jeopardized the lives of patients, a very large injection of water or insufflation of air should be made before the operation is commenced.

Treatment.—The number of drugs administered for the relief of constipation in infants is surprising, if not alarming. Castor oil, gray powder, calomel, senna, scammony, jalap, podophyllin, belladonna, rhubarb, cascara, besides the favorite powders of the different doctors, are all given in various combinations. For the nursling, in the majority of cases except in an emergency, they are useless, and should be discarded. The indications are to correct the condition either by attention to the mother or by a slight change in the food of the child, and to avoid laxatives.

After excluding congenital defects we should look to the mother for the cause. If an evacuation of the bowels does not occur within twenty-four or thirty-six hours after birth, a careful examination of the anal opening should be made; indeed, in some of the large lying-in hospitals a very small enema is given as a part of the baby toilet at the first dressing. This demonstrates at once the perviousness of the canal. Next let the mother be examined for a cause of constipation, and, by changing her diet, seek to correct her baby's habit. It may be necessary to administer a mild laxative to the mother; for, as a rule, simple constipation in the child should be overcome without giving it medicines or injections.

If a child has been provided with a wet-nurse and is constipated, the question will arise as to the propriety of changing to a wet-nurse with younger milk, in order to furnish more colostrum and less casein. Of course everything of a constipating nature, including starchy foods, is to be excluded from the diet of mothers or wet-nurses whose children are constipated.

If, notwithstanding these directions, the habit persists, and the child has but a single dry passage each day and this is attended with straining, some exceedingly simple remedy should be administered to the child. As the simplest of laxatives, I strongly recommend a little molasses or simple syrup in water, and where the passages are very dry and the child is known to perspire freely, we should suspect an insufficiency of water in its system, and to overcome this there is nothing better than pure water internally. I desire to emphasize this point. It is an affliction to deprive a child of water. It is not only a cause of constipation, but the deprivation of water sometimes amounts to absolute suffering on the part of the child. A baby is not always hungry when it cries; it may be thirsty. To feed a child when it is only thirsty, and not give it water, will sometimes aggravate a constipation. Let it be remembered, then, that one of the most efficient remedies in the treatment of children is water given two or three times during the twenty-four hours. To a child accustomed to a mixed diet, in place of water, oatmeal-water may be given for a time, in order that the child may be nursed less frequently.

If the measures already suggested do not give relief, of course other treatment must be adopted, and we come to consider local stimulants which may be introduced into the anal opening or into the rectum. Among them I notice the soap or gluten suppository, molasses boiled and moulded into little masses and introduced, and the nozzle of a syringe oiled and inserted and injections of very small quantities of glycerin or water or both combined. Bohn recommends, as preferable to any of the foregoing, injections of cold water three times, if needed, each day, then twice a day, and finally once daily until the cure is assured. Other authorities advise cold water as the injection, to which may be added a small amount of common salt. If enemata are necessary, either warm or cold, use small quantities, one or two fluidrachms of water, or from ten to twenty drops of glycerin to which may be added a little water. Large injections of any fluid should be avoided, because they not only dilate the colon and paralyze the lower bowel, but sometimes also produce discomfort in infant patients by crowding against internal organs and producing, among other symptoms, difficult respiration and interference with circulation.

As the child develops, and particularly as the process of dentition commences, a constipation which has been troublesome is sometimes entirely overcome. This is true if laxative medicines have been avoided and the bowel has not been injured by very large injections. In a few infants growth and nutrition seem to progress in every respect naturally with only a single passage each day, and with such it is not necessary to interfere. If drugs must be given to the nursling, nothing will yield better results than minute doses of calomel, or small doses of castor oil or of magnesium carbonate—gr. x to xv to ℥i of water and syrup—given in teaspoonful doses *pro re nata;* or a grain or two of the magnesia may be given in a little sweet milk.

In older children some cause may be apparent which could not be discovered in a nursling. It is needless to say that in all cases this should be removed.

In older children, too, we should see to it that the endeavor is made to inculcate the habit of regularity in attempts to evacuate the bowels. When fæcal matter descends into the rectum, producing some sort of irritation or fulness, as it does in older children when the effete stuff comes to have a greater consistency, nature should be listened to, and the evacuation encouraged by a daily regular habit. If these promptings are disregarded for a long time, they are liable to cease; the sensibility of the part is diminished, and a constipation difficult to cure is the result. A child of two or three years, and sometimes even younger, may be taught to expect an evacuation of the bowels at some regular time; and with this expectation and a regular habit it may be taught to exercise its will. Let there be, then, a co-operation of habit, expectation, and will, before we think of drugs. It is in children of this age that massage and methodical irrigation of the bowel are so highly beneficial. Baginsky prefers this treatment to any other; the same author deprecates suppositories, particularly the soap, as tending to produce local inflammations.

Children on a mixed diet should avoid the starchy foods and eat more soups. Use water freely, and a varied diet; let the food be somewhat coarse, well masticated and swallowed slowly; and avoid giving the same food repeatedly. If the digestion be good, more milk may be added to the food; a little oatmeal will increase its coarseness and a few drops of molasses make it slightly laxative. This may be changed from day to day to mush made from unbolted wheat-flour or corn-meal, or to bran in bread and milk prepared by soaking the bran in the milk, warming, and then adding the bread. Whey, when it can be obtained, is of great benefit. To children two or three years of age, stewed fruits or baked apples may be given. Small amounts of fruit, particularly grapes without skin or seeds, are now admissible, or figs, the Tamar Indien, and purgative biscuits made by the French. At this stage we advise home gymnastics, particularly if the nutrition is below grade, swimming, and salt-water bathing if possible. In any case, however, do not expect too much; ascertain the amount of food taken daily, and do not look for a greater quantity to be excreted.

Among the drugs which are useful in children of this age is calomel in small doses. Children invariably bear this drug well, and habitual constipation is always relieved by its occasional administration. It should not be given habitually to those afflicted with the strumous or rachitic diathesis. Castor oil or castor-oil paste,[1] or small doses of belladonna and of tincture of nux vomica, may be given; or the gray powder with a little bicarbonate of sodium, or powdered liquorice (pulv. glycyrrh. comp.) with sulphur, if there is any evidence of rectal irritation. The small doses of belladonna and nux vomica mentioned above will be found in combination very serviceable in giving tone to the bowel or for relieving spasm. According to some authors, these drugs also relieve flatus; in my judgment, however, nothing gives better results for this distressing symptom than magnesia and asafœtida.

---

[1] Made by rubbing together powdered acacia, castor oil, syrup, and glycerin, and flavoring with anise, vanilla, or other aromatics.

The glycerin treatment which has been suggested for both nurslings and older children is an old remedy recently revived. According to Dr. Althaus, it was probably discovered by Dr. Oidman, who kept it a secret until it was purchased by Dr. Anacker, who analyzed it and brought it to the notice of the profession. The theory of its action is as follows: glycerin brought in contact with the mucous membrane of the lower bowel withdraws water from it and causes hyperæmia and irritation of the sentient nerves of the rectum: this produces powerful peristaltic contractions and defecation.

The family physician should see to it that the older children do not eat those articles which are known to constipate. Forbid spices, cheese, dried fruits, and the coarser dry foods. Do not advise medicine for failure to evacuate the bowel every day, but encourage the attempt, with attention to the diet; practise rubbing and order exercise. If drugs must be taken, find the one which agrees with the patient, and then the dose which causes an evacuation; then gradually reduce the quantity of medicine till the diet, which has been corrected, keeps the bowel in a normal condition. The fluid extract of cascara sagrada, in doses of one or two drops, will be found an excellent remedy. For a child of two years, clear out the bowels with a powder containing two or three grains of calomel with a little compound liquorice powder; follow for a few days with carbonate of magnesium (ʒii to water ℥i) one to three teaspoonfuls each day till the bowels are relaxed. Then give non-astringent iron preparations, nux vomica, and possibly magnesium sulphate or cascara, until the cure is complete. Dr. H. H. Clark, of Iowa, believes that ipecac in one-grain doses, either alone or with small doses of calomel, is the remedy *par excellence* for constipation in children.

The headache and coated tongue, the nervous and feverish symptoms, and the dizziness, which we find associated with constipation and possibly diagnosticate as biliousness and indigestion, cannot easily be cured by bromides and neurotic remedies. First clear out the bowel of its accumulated filth, then give a remedy to act on the secretions, and afterwards give iron, nux vomica, and magnesia.

In constipation which has persisted for a very long time, with great distention of the bowels, the abdomen may be bandaged to aid in restoring tone. Galvanism or electricity may be used. In excessive distention, with symptoms of collapse and much heart-displacement, we may resort to puncture of the colon with a hypodermic needle.

Sometimes it will be necessary to produce a diarrhœa for some days in order to unload the colon.

Whenever the colon is blocked it must be cleared by the use of enemata. In chronic constipation always make an examination of the rectum: it sometimes reveals much to help in the diagnosis. Congenital deformities, never suspected, have been thus discovered.

If electricity is used, it should be remembered that Schillbuch (quoted by Jacobi) has found that the several portions of the bowels respond differently to the application of the faradic and of the galvanic current: the galvanic is usually the stronger. Local contractions result from the negative pole, peristaltic waves from the positive. Apply the negative pole in the rectum, and the positive over the abdomen along the colon. By massage or gentle kneading of the abdomen over the colon and in the direction of its peristaltic movements, muscular action is stimulated and the desired results are frequently brought about. This process should be repeated two or three times a day.

The treatment of constipation occurring as a complication of other diseases demands more space than is allotted to me, and a few words must suffice.

Cod-liver oil and syrup of the iodide of iron are particularly useful in the rickety and strumous diatheses. The oil is one of the best remedies for these diseases, and acts well for the constipation which is frequently incident. Indeed, cod-liver oil, two parts, and lime-water and the syrup of the lacto-phosphate of calcium, each one part, are regarded by Prof. J. Lewis Smith as meeting as many indications in the ordinary constipation of children as any other combination.

Children with indigestion associated with constipation should always have first a corrected diet, then pepsin in combination with muriatic acid, and cascara or compound syrup of taraxacum.

In anæmic children the mineral waters containing iron are particularly recommended by the Germans. The Friedrichshall is claimed not only to have saline aperient qualities, but also to be a tonic: it influences tissue-changes and promotes the excretion of uric acid. A mixture of sulphate of iron, sulphate of magnesium, and tincture of nux vomica will be very serviceable in these cases.

It is almost needless to say that accumulations of fæcal matter must be removed by the more powerful cathartics and by regular irrigation, which sometimes must be carried into or through the mass by means of a tube. An impacted rectum must be cleared by the use of the syringe, and occasionally digital assistance will be required.

TABES MESENTERICA.

By A. JACOBI, M.D.

The names by which diseases are known in modern pathology have come to be derived from their pathological anatomy in the same degree that local diagnosis has been brought nearer perfection. Symptomatic diagnoses and symptomatic terms are becoming rare; though it is true that there has crept into nomenclature an equally unscientific habit, which consists in applying to a newly-observed disease or complex of symptoms the name of their first observer—or inventor. Many formerly accepted as nosological entities have been given up as such; when we speak of dropsy, paralysis, convulsion, neuralgia, epilepsy, or atrophy we know perfectly well that we have to deal with a symptom, or a number of symptoms, requiring etiological details for their exact recognition, and special and varying indications for the treatment of individual cases. But until a very late period "tabes mesenterica," or "tabes mesaraica," has been accepted as a term applicable to a particular set of symptoms and limited anatomical changes by which it could be easily recognized. The following pages will be dedicated to showing that the pathological anatomy of mesenteric tabes is by no means the same in all cases, and that the term itself ought either to disappear entirely from our indexes or be recognized as merely a convenient expression for a complex of more or less similar symptoms.

Among those, mostly older, celebrities who were of the opinion that imperviousness of the mesenteric glands was a satisfactory explanation of tabes mesaraica, that patients die because the lacteals are no longer able to take up from the food a sufficient supply of nutriment, and that they die of starvation, are Thomas Watson, Cullen, and Bichat. The latter modified the general opinion in this, that he defined tabes (*carreau* of the French) as the engorgement of the glands of the abdomen, mostly occurring between the second and eighth years, painful or painless, complicated with digestive disorders, distention, diarrhœa, and vomiting, which, however, did not result in the non-absorption of chyle except in the later periods of the disease.[1] Cruikshank, as early as 1790, thought this blocking up of the lymphatic circulation very improbable, and Guersant formulated his hesitation in accepting the exclusive obstruction theory by declaring that the very diagnosis of the condition of the glands was always difficult; that the examination of all the viscera often resulted in the discovery of changes which led to the results attributed to glandular disorders exclusively; that he was not aware of a single case of disease of the mesenteric glands not attended with complications; that, moreover, there were many glandular disturbances without nutritive disorders; and, finally, that the mesenteric glands were not the sole roads for the admission of chyle. Besides, in his own reports, and in those of his followers, and in the experience of all those who have compared morbid symptoms during life with the evidences of post-mortem examinations, there are many cases in which, together with the glandular changes, or independently of them, the acute, subacute, or chronic inflammation of the peritoneum, either general or local, and mostly of a tubercular character, was the only anatomical anomaly underlying the symptoms of "mesenteric tabes."

---

Symptoms.—The main symptoms common to every form and case of "tabes mesenterica" are atrophy and tumid abdomen. Emaciation and atrophy reach a degree hardly ever met with in any other morbid condition. The subcutaneous fat disappears rapidly. The skin is thin, flabby, and inelastic; round the limbs it is loose and hangs like a bag; when taken up between the fingers it retains the fold raised in the lifting. In the beginning the muscles can be recognized; afterwards even they emaciate to such an extent that their outlines disappear, and those of the bones are distinctly perceptible. The eyes lie deep in the orbits, and have a peculiarly dry and hungry look; the bones of the face, with the thin, flaccid, dry and scaly skin over them, take on a terribly senile expression. The surface is mostly cool, the limbs are cold, the cutaneous veins very distinct and blue, much dilated over the chest and still more so over the abdomen. The voice is thin and tin-like, the cry mostly tearless, the pulse slow (from exhaustion of the heart-muscle) or more frequently rapid, thin, and compressible. The lymph-bodies of the neck and the inguinal region, sometimes also the axilla, are tumefied.

These symptoms are more or less common to all cases. There are many, however, which exhibit numerous variations in important particulars. Appetite may be ravenous or entirely lost. Some begin with little or no diarrhœa, but in all the stools are fetid. The majority, however, commence with a severe form of intestinal catarrh, attended with numerous offensive discharges. The peculiar odor, foul, musty, pungent, ammoniacal, is due in part to acids formed by the fat which has not been absorbed, sulphides, and other products of putrefaction. In the further development of the morbid condition there may be constipation, but diarrhœa is more frequent. It may not be very copious nor the evacuations very numerous. There is tenesmus in some, with but little substance; others are large, and expelled suddenly, in an instantaneous gush. The temperature is in some cases normal or even subnormal, in others elevated; when it is quite high, the cheeks and scleroticæ may become injected. The tumid belly is absolutely painless in some, very sensitive in others; the latter mainly in those who have an elevation of temperature. The large size of the abdomen, with its nets of dilated veins, contrasts fearfully with the atrophied condition of the limbs. It is large enough to press the diaphragm upward and interfere with the functions of both heart and lungs. The nature of the tumefaction, however, varies: it is tense or flabby, hard or soft, doughy or firm, uniform or irregular. Nodules or lumps of different shapes and sizes may be discovered by palpation. They may be spherical; flat, so that the hand can be run under the cake; superficial, near the abdominal wall; or deep-seated, in close neighborhood to the vertebral column. Gentle percussion will reveal tympanites all over, both on the top of the protruding abdomen while the child is on his back, and in the flanks; or there are one or more areas of relative dulness corresponding with a solid mass discovered by palpation; or there is dulness in both flanks, varying with changes in position, thus indicating the presence of fluid, which, moreover, can be made out by its fluctuation. Great care, however, has to be taken lest the presence of solid tumors in a flank give rise to the diagnosis of fluid, or lest intestines containing gas which have been glued to the abdominal walls disguise entirely through their lymphatic percussion-sound the presence of ascites.

Other symptoms may be present, such as œdema, through thromboses in small veins; extensive dulness belonging to fatty liver; albuminuria and the usual microscopic changes of the urine encountered with nephritis; local inflammations of the abdominal surface connected with abscesses which are occasionally, though rarely, the final stages of certain forms of peritonitis; and cough depending on tubercular disease of the lungs.

The variety of symptoms belonging to "tabes" points distinctly to different morbid processes. The gradual beginning, slow and feverless course, with but little disturbance of the bowels and other organs; the connection with a severe form of enteritis, continuation of diarrhœal discharges during the beginning and growth of tumidity, and moderate or high temperatures during the course of the morbid process; and the tumidity of the abdomen, with emaciation following chronic cough and repeated attacks of catarrh, and terminating either in fatal exhaustion or in acute peritonitis, appear to prove that there are several distinct forms of "tabes," depending on different causes and attended with varying anatomical alterations.

Pathology.—Former essays in this work, particularly those of Dr. Ashby on scrofulosis and my own on tuberculosis and phthisis, have explained the changes taking place in the lymph-bodies. Therefore only such brief remarks will be made here as refer directly to the mesenteric glands. Most of the first changes occurring in them are of an inflammatory nature; they are secondary in character; indeed, the primary changes are mostly neoplasmatic, and particularly sarcomatous. As in other glands, the inflammation may be a simple one and uncomplicated, or suppurative, or fibrous, or caseous, or tubercular. Simple adenitis is occasioned by any kind of irritation. Like an eczema of the head or a nasal catarrh which lights up adenitis of the neighborhood, a simple intestinal catarrh, with diarrhœa from any cause whatsoever, produces it. The first change consists in dilatation of the blood-vessels, with reddening, softening, and succulence of the tissue, endothelial changes in the lymph-spaces, and new formation of cells. Afterwards the red discoloration is replaced by a grayish-white color, now and then interrupted by small blood-points which will turn into pigment, and the difference between the cortical and medullary substances fades or disappears. At the same time the capsule gets tense over its swelled contents. These are the cases which are amenable to a complete recovery. But suppuration, induration, or necrosis of the tissue is often met with. The latter is a frequent occurrence in typhoid fever, in which the lymph-bodies of the abdomen play a similar part to what we observe both more frequently and more extensively in the glands of the neck, under the influence of diphtheria.

Suppuration of inflamed glands is more frequent near the surface than in the abdominal cavity, where they are less exposed. Still, it does occur there, though mostly in putrid and septic processes. Caseous and calcareous degeneration is noticed in a certain number of instances.

Fibrous induration of lymph-bodies is of frequent occurrence in every region of the body. It is the usual result of repeated irritation. The constant hyperæmia of a chronic intestinal catarrh or of frequent acute attacks precludes the return to normal circulation. Then the substance of the glands becomes hard, dense, and white, the hyperplastic connective tissue compresses and atrophies the cells of the parenchyma, the capsule becomes thick and indurated, and the organ retains nothing at all of its former shape, size, and function. In this condition when the change has gone beyond cell-proliferation, and new tissue has been fully organized, it is no longer amenable to treatment.

The tubercular form of inflammation is very seldom of a primary occurrence. In it the diseased gland is enlarged, nodulated, and contains small round cells, or flat epithelioid cells with large nuclei, and frequently giant cells. The caseous and tubercular forms, while it was Virchow's original inclination to distinguish between the two, are considered identical, or mostly so, by Schüppel, Rindfleisch, Orth, Cornil, and Koch.

Though it is rarely of a primary character, tuberculosis of glands, both mesenteric and others, is frequent; but to render a gland tubercular there must be an absorbing surface accessible to the virus and ready to admit it. A healthy mucous membrane absorbs no poison. It requires an open wound, such as a chronic eczema, or a chronic bronchial catarrh, to permit of a free access to the neighboring gland. Thus it is that the glands of the neck and the tracheal and bronchial glands are so very liable to become tubercular. The mesenteric glands are less exposed. It is true that the tubercular poison may pass the stomach undisturbed, but it is certain that tubercular enteritis and adenitis seldom result from it directly. Indeed, even the diarrhœas of phthisical patients, who swallow their own bacilli constantly, are not so often of a tubercular nature as they are the mere result of the local irritation produced by the presence of copious pulmonary discharges on the intestinal mucous membrane.

Only when the local irritation has persisted for some time and produced erosions has a virus an opportunity to locate and fasten itself in the injured epithelial layer. In that case the tubercular invasion may lead to serious results though the lesions of the surface have healed.

Thus it becomes evident not only why it is that a primary tuberculosis of the intestine, and the secondary tuberculosis of the mesenteric glands, by the introduction of tuberculous food, may take place, but also why they are relatively rare. Indeed, the cases which appear to be conclusive are by no means so. For, while we may suspect that infected meat or milk has occasioned a tuberculosis, that very case may have been infected either through a wound of the lips, mouth, or throat, or by simultaneous inhalation. Thus the suspicion that a case is one of intestinal contagion is more readily entertained than it can be proved. Schottelius[1] fed ten families, consisting of one hundred and thirty persons, on tuberculous meat, which was taken raw sometimes, for two years; in eleven years none of them died of tuberculosis. Thus, while there is no doubt as to the occasional occurrence of tubercular infection by meat or milk, the cases must be well weighed before they are decided affirmatively.

Besides the simple secondary hyperplasia of the mesenteric glands resulting in obstruction, and the tubercular infiltration terminating in the same disturbance of function,—besides its infectious character,—there is a third condition which leads to the symptoms called "tabes mesenterica," viz., chronic tubercular peritonitis. It is quite frequent, but its symptoms may vary in duration and severity. While the child is emaciated, sometimes to a fearful extent, the abdomen is tumid, elliptic, its surface shining, the surface-veins dilated, the umbilicus expanded and flattened. There is sometimes ascites; sometimes hard and circumscribed tumors, or the intestinal convolutions, may be distinctly felt or seen. This tumid condition is even liable to persist when tubercular meningitis makes its appearance in the course of time. There may be colic and diarrhœa, or they may be absent. The temperature may be normal. Slight changes in the afternoon ought to be ascertained by inserting the instrument into the rectum. This condition may last many months, even a year; it is capable of vast improvement, and may terminate in recovery, though with a low standard of vitality. This capability of recovery, with which the experienced practitioner and pathologist has long been acquainted, has surprised the surgeons, now and then, who opened the abdomen under a mistaken diagnosis, found tubercular peritonitis, sewed up again, and concluded that when the patient recovered it was because, and not in spite of, their uncalled-for operation. At the present time, however, we are justified in the belief that only those cases of chronic peritoneal tuberculosis will have a chance which are local, and not the result of general tubercular infection.

---

[1] Virchow's Archiv, vol. xci.

Diagnosis.—In estimating the size and tumidity of a child's abdomen, we must not lose sight of the fact that it is normally larger in proportion than that of the adolescent or the adult. The child's pelvis and chest are less developed, its liver large. The shape of the abdomen is tun-like, its vertical length one-third of the length of the body, while in the adult the proportion is one-fifth. A high degree of tumidity may be due to constipation, mainly that form which originates in oversize of the sigmoid flexure, or in expansion of the intestine depending on muscular weakness. The main cause of the latter is rhachitis, the first principal features of which, when developed at an early date, are costiveness, meteorism, and flabby muscular texture. Other causes are flatulence depending on improper food and fermentation-processes in the bowels, or insufficient peristalsis, or the presence of scybala; also the presence of ascites depending either on cirrhosis or perihepatitis or generalized peritonitis, the first of which is the less frequent cause; or oversize of abdominal organs, such as the liver or bladder; also either cystic (urachus or echinococcus) or solid tumors. Among the latter fibroma, enchondroma, myxoma, and lipoma are quite rare and therefore not of clinical importance; carcinoma is not uncommon, but sarcoma is more frequent. There were, up to 1884, forty-three cases of sarcoma of the kidney on record.[1] Tubercular disease and tubercular tumefaction are very much more common. It is true that isolated tubercular tumors, mainly those of the mesenteric glands, are quite rare, but they do occur, uncomplicated or, mostly, complicated with other lesions of an inflammatory character. This complication of glandular enlargement with peritonitis may lead to very serious results, even beyond the tubercular infection. A girl of two and a half years, of healthy family, who previously suffered from aural discharges and measles, and afterwards from anæmia and general malaise, was taken with abdominal pain and distention, constipation, and vomiting of mucus and purulent material. She died after an illness of three days. The autopsy revealed caseous mesenteric and retro-peritoneal glands of the size of pigeon's eggs, bending upon itself and gangrene of the sigmoid flexure, peritonitic adhesions along the descending colon, the sigmoid flexure, and the rectum, and complete obstruction, by compression, of the ileum.[2] Similar occurrences are not at all rare, though mostly not so striking as the one just related. Indeed, adhesions between the intestines themselves, or the intestines and the parietal peritoneum, or peritonitic exudation with hemorrhages, or infiltrations of the omentum which result in hard nodulated tumors located above the umbilicus, are quite common, and form large masses together with the infiltration of the glands themselves. Such peritonitic exudations may be either simply inflammatory or tubercular, small or large, hard or soft, local or generalized to such an extent as to fill the whole abdomen.

---

[1] A. Jacobi, Sarcoma of the Fœtal and Infant Kidney, Transact. Internat. Congress, Copenhagen, 1884.

[2] Th. Pauli, Jahrb. f. Kinderheilkunde, 1889, xxix. 77.

The diagnosis of tubercular peritonitis, or peritoneal tuberculosis, is apt to be quite difficult. There are many chronic cases which cannot be differentiated from non-infectious peritonitis and other inflammatory processes. Besides, many of the caseous tuberculizations are small, and thereby inaccessible to an accurate physical examination. They, and the rare cases of primary tuberculosis of spleen, liver, bile-ducts, peritoneum, and intestine, are to be inferred rather than diagnosticated. But there are cases of tumid belly with atrophy, of both an acute and a chronic character, in which the nature of the affection can be made out with some degree of certainty. When the distention of the stomach appears after an intestinal catarrh, when it continues after the diarrhœa has ceased in frequency, the stools either improving in character or remaining offensive, when the temperature remains high and the symptoms (occasionally) exhibit a "typhoid" character, with (now and then) delirium and frequently a dry tongue, the existence of an acute attack of tubercular peritonitis is probable. This diagnosis is rendered the more probable by the presence of some other symptoms. Among them are cough, sometimes slight, short, and hacking, sometimes moist and frequent; the presence of pulmonary symptoms or dulness over the manubrium sterni or below one or both of the clavicles, pointing to swelling of the tracheal or bronchial glands; a concomitant history of tuberculosis in the family; and a more intense degree of emaciation than the brief duration of an intestinal catarrh would justify. Still, mistakes are possible even then. The frequent complication of peritoneal tuberculosis with fatty liver and parenchymatous nephritis may obscure the clear comprehension of the case. "Scrofulous" glands occurring round the neck may be, and mostly are, non-tubercular, being the result of non-infectious irritation of the scalp or nasal cavities; the tumefaction of the inguinal glands is too frequent to be of much account.

Prognosis.—The prognosis is always uncertain except in the very worst cases. It is absolutely fatal when the "tabes mesenterica" means peritoneal and glandular tuberculosis complicated with, or depending on, generalized tuberculosis; when the temperature is permanently high, and exhaustion extreme; when diarrhœa remains copious and offensive, the heart very feeble, and the intra-abdominal exudation has resulted in very extensive induration. A case occurring in a healthy family, in a child that does not suffer from cough or other pulmonary complication, but develops its emaciation and tumid abdomen after a protracted, though uncomplicated, diarrhœa, furnishes a more favorable prognosis. For in such the diagnosis of a mere—non-infectious—hyperplasia of the mesenteric glands can be made with great probability. In such, even large indurations will be absorbed gradually. When the diagnosis of chronic peritoneal tuberculosis has been made, the case is less promising; still, in it the possibility of recovery, or partial recovery, is not excluded. Indeed, the results of laparotomies, such as have been alluded to before, hold out a certain amount of hope even in those cases in which the diagnosis could be made with perfect accuracy.

Treatment.—A healthy infant or child cannot fall sick with any of the symptoms of "tabes mesenterica." Thus prevention consists in taking all the measures calculated to preserve the general health of the baby. Foremost among them is the selection of proper food: all the rules and regulations detailed in other parts of this work, which refer to the raising on breast-milk and appropriate artificial food, must be conscientiously obeyed; farinaceous substances allowed in but moderate quantities; casein, which is a frequent irritant of the intestinal mucous membranes, limited to its proper percentage; and fat administered in no greater quantity than is contained in the natural nutriment of the nursling. Weaning is to take place at the legitimate time, which has mostly arrived when a few teeth have made their appearance. Good air and attention to the condition of the skin (cool bathing and friction, protection by warm clothing, and avoidance of draughts) aid in enabling the young to resist injurious influences.

The early symptoms of rhachitis indicate a thorough anti-rhachitical treatment (animal food, phosphorus, and iron), and diarrhœa, no matter from what cause, must be relieved immediately. Again I insist upon the danger incurred by allowing the catarrhal or inflammatory irritation of the mucous membrane to remain unchecked; for it is because of this that the neighboring glands begin to swell, or that bacteric invasion takes place. But not diarrhœa alone is connected with hyperæmia and its dangers; constipation also may be both the result and a cause of extensive congestion and irritation. Sometimes glandular swelling may appear without an apparent cause. In a healthy family the thirteenth baby, after having been subject to habitual costiveness, was laparotomized because of intussusception. Thus it happened that the mesenteric glands could be leisurely inspected and examined; they were swelled to the size of beans and hazel-nuts.

To prevent the tubercular form, cow's milk and meat must not be administered unless exposed to boiling heat. It is true that there are not many cases of infection by these agents, but the few ought to be avoided. Cream, buttermilk, and cheese cannot be submitted to the same preventive measure, and must be used with some caution. The different forms of scrofula ("erethic" and "torpid") must be treated according to the methods discussed in other essays; it is in them that animal foods, malt, iron, cod-liver oil, and cereals without or with milk, are indispensable. Whenever possible, a change of climate ought to be advised. Local tuberculosis in glands or in bones must be extinguished by an operative procedure; and a chronic eczema should be made to heal.

In chronic cases, in which changes in the mesenteric glands can be safely diagnosticated and the existence of tuberculosis excluded, iodides largely diluted may be administered for a long time. The potassium, sodium, and iron salts have their own indications, and may be combined. They are particularly demanded in patients who have previously suffered from the torpid, or adipose, form of scrofula. They may be used externally, in baths regularly given. It is here that natural springs, such as St. Catherine's and Kreuznach, can be employed to advantage. In the tubercular form arsenic ought to be administered in small doses for weeks or even months. Fat (cream, cod-liver oil) does better here than in the simple hyperplastic form, but in every instance we ought to remember that indurated mesenteric glands absorb but a small quantity. Whenever enteritis remains active, the eroded or ulcerated mucous membranes require antifermentative treatment. In that chronic form small doses of calomel are less efficient than bismuth, with or without resorcin, and small doses of opium. Naphthalin and salol may be tried, but generally are not well tolerated. Nitrate of silver, one-fortieth to one-twentieth of a grain every two or three hours, may be given for a week. Counter-irritants have a less happy effect than warm applications (moist or dry) and warm bathing. As may be judged from the remarks I made on laparotomy in connection with peritoneal tuberculosis, it cannot be recommended as a remedy until many more unbiassed observations shall have been gathered. In ascites paracentesis must not be performed unless urgently required, for many a case has been absorbed without any surgical interference.

PARASITES OF THE INTESTINAL CANAL.

By W. T. COUNCILMAN, M.D.

History.—Any study of the progress of our knowledge of the intestinal parasites shows that here, as in all other departments of medical literature, the same fluctuations of opinion prevailed as to the importance of the part which these parasites played and the frequency with which they were encountered. The development of our knowledge in this branch of medicine, as shown in the literature of the subject in the last one hundred and fifty years, is closely analogous to the development of our knowledge of the bacteria in the last twenty years.

There has always existed the desire to find some apparent cause to account for given phenomena, and, in the absence of any other known cause, the intestinal parasites, even some of the most harmless of them, were considered the cause of the most varied diseases. Dysentery, scurvy, hydrophobia, and even some of the most dangerous epidemics of the Middle Ages, were regarded as due to intestinal parasites. When these were not discovered, their existence was supposed. The discovery of the itch mite and the proof that this was the cause of that wide-spread disease gave importance to this belief.

Then, as was most natural, there came a reaction. The presence of the parasites was acknowledged, and it was believed that they were injurious, and could even endanger the life of their host, but their connection with any known form of disease was denied. Many, indeed, denied that they were attended with any danger to the individual, and some went so far as to argue that they exerted a beneficial effect, in that they assisted digestion by increasing the secretion of mucus and stimulating the peristaltic action of the intestine. These latter views were held by some of the most distinguished of the investigators, but many of the physicians held to the old ideas. To many, when they did not know anything of the real nature or cause of a disease, it served as a cloak for their ignorance to speak of worm-irritation, worm-fever, and worm-diseases in general. Others, while they did not deny that certain pathological conditions in the intestine were associated with the presence of worms, asserted that there was no causal connection between the two, and supposed that there could be certain pathological conditions which predisposed the intestinal canal to the production of worms. Bremser, one of the most celebrated of the helminthologists of the time, designated under the name of diathesis verminosa a condition of the alimentary canal accompanied by disorders of nutrition and digestion in consequence of which material accumulated in the intestine which was favorable to the production of worms. It was even held by such distinguished investigators as Rilliet and Barthez that this worm-diathesis could exist without the presence of worms. It was only after exact scientific work by patient investigators, accompanied by experiments on animals and man, that the life-history of most of the intestinal parasites, and the part which they play in the production of disease, were put on a firm and scientific basis.

The subject of intestinal parasites has a further importance because the first proof of the connection of a typical infectious disease, trichinosis, with a living germ, the trichina spiralis, which in its adult life is an intestinal parasite, was acknowledged at a time when the causal connection of bacteria with disease was denied by very many, although the proof of it was just as definite and positive as that of the connection between trichinosis and the trichina.

Pathology and Clinical History.—The pathological conditions produced by the different intestinal parasites depend on the nature of the parasite and on the part of the intestinal canal which it inhabits. Thus, it is natural that the anchylostoma duodenalis should produce a set of symptoms different from those produced by the ascaris lumbricoides, and this, again, symptoms different from those produced by the oxyuris vermicularis.

In regard to the manner in which the parasites exert an influence on their host, we have principally three matters to consider. In the first place, they grow and exist at the expense of their host. They exert a local influence by their bulk, in that they make pressure on the parts around them and may close canals in which they live. Their presence and their movements may produce pain, and may variously affect the physiological functions of the intestine; they may also, by irritation of the sympathetic nervous system, give rise to symptoms of the most varied character. It is not known whether, like the bacteria, they produce certain chemical substances, ptomaines, which have an injurious action, but it is probable that they do so.

The first of these modes of action, the withdrawal of nutriment from the host, is generally of little or no importance, but under certain circumstances, and when the host is a delicate, badly-nourished child, this may amount to something. Leuckart estimated the weight of a bothriocephalus latus twenty-two feet long to be twenty-seven and a half grammes, and that in the course of the five or six months that it took to reach this length it probably consumed six or seven times its weight of food,—a quantity which is scarcely worth mentioning. When the parasites are present in great numbers, as sometimes happens in the case of lumbricoid worms, five hundred or more of which have been seen in a single case, estimating, as

Leuckart does, the yearly consumption of one at three grammes, it will be seen that so great a number as this must withdraw a considerable amount from the nutrition of the body. When the worms do not live on the intestinal contents of the host, but, attaching themselves to the mucous membrane, directly take the more valuable blood, the case is much more serious. Thus, the anchylostoma duodenalis produces the most severe forms of anæmia not only by the direct withdrawal of blood, but also by the subsequent hemorrhage from the bites which it makes.

The effects which the parasites produce acting by their bulk alone, as in closing the lumen of canals, are of little importance. The most serious of these are when the round worms, leaving the intestine, wander into the biliary or pancreatic ducts or into the air-passages. There may also be exceptional circumstances in which such masses of lumbricoids are present that their bulk may in some place fill the entire lumen of the intestine and produce strangulation.

The most important effect of the parasites is the irritation which they produce of the nerves of the intestinal canal. This is shown by various symptoms, some of which are referable to the intestine, but others apparently have not the slightest connection with it. All these nervous symptoms are more pronounced in children than in adults, because the nervous system in the former is so much more excitable than in the latter.

Many of the intestinal parasites pass through an embryonic condition in which the embryo lives under relations which are very different from those which suit the adult parasite. In some cases the real danger to the host is not connected with the presence of the adult animal, but with the embryo. Thus, the adult trichina in the intestinal canal produces symptoms which, though severe, are attended with no danger to life, but a dangerous and often fatal set of symptoms begins with the wandering of the embryos into the muscles.

Modes of Infection.—The results of the scientific study of the intestinal parasites have been particularly shown in the increased knowledge of the modes of infection, and the most valuable results in prophylaxis have been the outcome of this. Many of the parasites pass through different forms in the course of their development, and these different forms for the most part require different hosts. Nothing has been more clearly shown than that we derive many of our parasites from the domestic animals. Sometimes the parasite passes over to us in an embryonic form, sometimes in the form of eggs which find in our bodies suitable conditions either for complete development or for development up to a certain degree. Thus, we become infected with one variety of tape-worm from eating the embryos which appear in the hog in the form of small cystic animals in the muscles, and with another variety from eating beef in which a similar phase of embryonic development is found. Infection takes place from the use of animal food containing the embryos of the parasites, and also from introducing the eggs in various ways into the intestinal canal. Thus, it is not uncommon to have vegetables fertilized by the use of liquid manure which may contain great numbers of the eggs of certain parasites which reach the intestines when the vegetables are eaten in the form of salads. There is not so much danger, or none at all, when the vegetables are cooked thoroughly. The drinking-water may also serve as a vehicle for infection. The eggs or embryos of parasites after being passed out with the fæces find their way into the streams, being washed there by the rains, and in this way enter into the water-supply of cities. This mode of infection may be guarded against by filtering the water, for none of the eggs will pass through properly-constructed filters.

Another important mode in which the infection may be kept up is that by self-infection. The eggs of certain of the parasites are continually passing from the intestinal canal, generally in the fæces, and in persons of uncleanly habits these eggs may get on the fingers and thus again be taken into the mouth, and develop in the intestinal canal. This is most common in the case of the small oxyuris worms. It is almost the rule to find the eggs beneath the finger-nails of persons afflicted with this parasite. The cysticercus cysts found in man result from swallowing tape-worm eggs, and frequently the eggs are derived from a tape-worm in the same individual.

It is natural that, so much depending on cleanliness and the proper preparation of the food, the intestinal parasites should be so much more common in those lands where the people live more in a state of nature and do not use so much care in the selection of their food. Thus, the echinococcus-cyst, produced by eating the eggs of the tænia echinococcus, a common parasite of the dog, is very common in Iceland, where the people live on intimate terms with the dogs. In Abyssinia, where the habit of eating raw beef is very prevalent, the tænia mediocanellata, the cystic embryo of which is found in beef, is very common. In all cases the eating of raw or underdone meat, and of vegetables in the form of salads, offers a much greater chance for infection than when the food is thoroughly cooked, since cooking destroys both the eggs of the parasite and the embryos. Many of the parasites are more common in children than in adults. This cannot be because the intestine of the child offers a better place for the growth of the parasite than that of the adult, but the chances of infection in the child are greater. The child has for itself no habits of personal cleanliness, and is not so careful as to what it puts into its mouth.

Certain lands are the homes of particular parasites. One of the varieties of tape-worm, the bothriocephalus latus, is found only in certain parts of Europe, and another variety only in Greenland. It can only be that the conditions for embryonic development are found here alone. Other parasites, though existing everywhere, are more common in certain lands. This may be due to the habits of the people, or to the eggs finding outside of the body more suitable conditions for development. Thus, the lumbricoid worms are more frequent in warm climates, because their eggs find in the heat and moisture the suitable conditions for reaching that period of development which they must have before they can exist in the intestine.

TAPE-WORMS.—The tæniæ are long flat worms, composed of a number of segments which are slightly joined together. The segments are flat, and have some resemblance to pumpkin-seeds. The length of the worm may reach sixty feet, and the segments number many hundred. The head is round, and about the size of the head of a pin. Immediately behind the head the neck is at first narrowed and then increases in width. The neck has transverse constrictions, but the segments proper do not begin until some distance farther down. In each segment there are complete male and female organs. The genital openings are on the side of the segment, the male being directly over the female. These openings are on the alternate sides of adjoining segments. There are not usually more than three or four hundred sexually-mature segments in the worm. The constrictions in the neck become segments, the sexual parts gradually developing in them. The head of the worm is somewhat complicated, and the several varieties of tænia are distinguished from one another by the structure of the head and of the genital organs. The tænia solium, the pork tape-worm, has a slight projection at the apex of its head, and around this a series of chitinous hooks; below these are four powerful sucking disks. The tænia mediocanellata, the beef tape-worm, has a blunter head than the tænia solium and is without the circle of hooks. In both there is a system of water-canals which extend from the head through all the joints of the body. The tænia solium is nearly always found alone, whence its name. The French call it *ver solitaire.* Several of the tæniæ mediocanellatæ may be found in one individual.

The tænia solium is produced by eating pork which contains the embryos in the form of small cysts. These cysts represent the head of the worm and a single segment which is dilated to form a vesicle. The pork containing the cysts is known as measly pork. When such pork is eaten uncooked or insufficiently cooked, which often is the case with sausages, the head attaches itself to the mucous membrane and the worm continues to grow by the formation of segments. The eggs are not separated from the segments in the body, but the segments are discharged entire, either singly or in chains of several. They generally pass away with the fæces, but they may pass independently. Persons frequently have their attention called to the presence of the worm by finding these segments in the clothing. When the eggs are swallowed they undergo a partial development and reach certain parts of the body, where they become the cystocerci cellulosæ. This development of the eggs may take place in man as well as in hogs. The embryonic form of the tænia mediocanellata is found in the beef, and the worm is produced by eating such flesh in a raw or underdone condition. Another variety of tape-worm found in man, the bothriocephalus latus, has a very limited geographical distribution, being found only in Russia, Sweden, Holland, Switzerland, and some parts of Germany. Little or nothing is known about its development, but it is probable that it passes through an embryonic condition in certain fish and is produced by eating these. It is the largest of the tape-worms, having a length of from twenty to sixty feet, and the segments are an inch or more in breadth. The tænia mediocanellata is more common in America, England, and France, owing to the fact that in these countries beef is often eaten not sufficiently cooked to destroy the embryos. In Germany the tænia solium is more common, because much pork is eaten either raw or imperfectly cooked in the form of sausages.

The tape-worm is never seen in nursing children where milk forms the exclusive diet. It is often met with from the age of five to fifteen years, and is most common from fifteen to forty. It is very curious that females are more subject to it than males, for there is nothing in the diet or the mode of life in the two sexes which can give any explanation of the fact. Warruch found in two hundred and six cases of tape-worm twenty-two in children. The relation of the sexes in the whole two hundred and six cases was seventy-one males to one hundred and thirty-five females.

Symptomatology.—In some cases the tape-worm produces no symptoms, and the host is made aware of the presence of his guest only by the passage of the segments. There are no symptoms which are absolutely diagnostic of the worm. Those which are generally enumerated may appear together or singly. There may be various disturbances of digestion, irregular appetite, unpleasant sensations in the belly, which in young children may increase to colicky pains and gastralgia. Reflex symptoms, convulsions, and even chorea and epilepsy, may appear, and are more frequently seen and more severe in children than in adults. Other disturbances referable to the nervous system are giddiness, buzzing in the ears, itching at the nose and anus, sometimes an increased secretion of saliva, nausea, especially when the stomach is empty, and even vomiting. Many patients complain of feeling the movements of the worm in the intestine, or of a sensation as of a ball being there. With all these symptoms the general health of the patient may remain perfect, but where there is much disturbance of digestion there may be a slight degree of wasting and pallor. Weak children suffer much more from the parasite than do those that are strong and well nourished. There may be various psychical disturbances: children are often fretful, peevish, and impatient. Often there is pain around the umbilicus, which radiates upward to the epigastric region. Sometimes this pain returns at regular intervals and is generally quieted by eating. The appetite is irregular: in some cases it is very poor, in others it is increased to regular boulimia. Sometimes the pain in the intestines is accompanied by a considerable degree of meteorism, and the swelling of the belly is very unpleasant. The reflex symptoms are said to be more common and more severe in cases of bothriocephalus than in either of the other varieties of tape-worm. In addition to the nervous symptoms mentioned, there may be nervous trembling, hysterical phenomena, a dry, convulsive cough, disturbances of vision, hyperæsthesia or anæsthesia, disturbed sleep, crying and calling out in the sleep, etc.

Diagnosis.—There is nothing pathognomonic about these symptoms. A combination of neurotic symptoms, a tendency to colicky pains, and itching around the anus may lead one to suspect the presence of a tape-worm, but a certain diagnosis can be made only by evidence of the segments. When large masses of the worm have passed away, all the symptoms become much milder, and may even disappear for weeks or months. The entire worm, with the exception of the head and a small part of the neck, may be passed, and the symptoms disappear until a new growth of the worm takes place. A complete spontaneous recovery, with the passage of the entire worm, is very seldom seen. It is certain that the tape-worm, like all other living beings, must die after a time, but its duration of life is unknown, and in any case is a very long one. Cases have been known where the worm has existed for twenty years. After one has lived in the intestines for a very long time, all the symptoms occasioned by it become very much lighter or may even disappear altogether.

Prognosis.—The prognosis is always good so far as danger to life is concerned, but sometimes the tape-worm proves to be a guest that cannot be easily got rid of.

Treatment.—Care must be exercised in the use of remedies, especially in children, from the ease with which gastric disturbance may be set up. All tape-worm remedies, especially the most efficacious, have the disadvantage that they are liable to disturb the stomach. They should never be given on a venture, on a supposition from the symptoms that there may be a tape-worm present, but the diagnosis must be made certain by the presence of the segments. All these remedies act by killing the parasites, and some general rules for giving them may be found to be of advantage. In general it will be found more difficult to expel the worm in children than in adults, principally for the reason that the treatment directed against it in the former cannot be so heroic. One of the difficulties in the way of treatment is that the medicines are so unpleasant to take. It is better that a period of fasting should precede any attempt at therapeutics. This is supposed to weaken the parasite, and then the medicine will have a greater effect on the weakened animal. Often medicines seem more effective after large numbers of segments have been passed. A brisk purgation with castor oil should follow several hours after the anthelmintic has been given.

An old remedy against the worm is the bark of the pomegranate. Care should be taken to secure the fresh bark, as it soon loses its qualities when kept. The powdered bark should be macerated with an equal amount of water and this reduced by boiling to half the quantity. Very young children should be given half a teaspoonful of this decoction, and those over ten years old may be given a full teaspoonful. In order to prevent vomiting, a little of the syrup of orange-peel or ginger may be added.

The root of the male fern, *filix mas*, is a remedy which is much regarded.

It may be given in the form of a powder, the dose being from ten to ninety grains according to the age of the patient, either in a single dose or in divided doses. In general, better results follow the administration of one large dose than of several smaller doses.

Kousso is a remedy that of late years has been used with great success in the treatment of tape-worm, having been introduced into Europe from Abyssinia, where the disease is very common. It is a remedy which has some disadvantages, particularly with children, as it is very disagreeable to the taste and is apt to produce nausea and vomiting. An infusion is made of the flowers of the plant. Two to six drachms of the powdered leaves should be added to five or six ounces of boiling water, and, after cooling, the whole should be taken in divided doses, being careful to shake the mixture before taking. If no stool follows in three or four hours, a purgative should be given. A useful form of administration has been found in tablets made of the compressed leaves.

Pumpkin-seed is a useful remedy and one not disagreeable to take. The hull should be taken from the seeds, and the pulp rubbed with water to a thick mass, and of this from one to two ounces may be given in a single dose, and in a few hours followed by a dose of castor oil. Should the worm not be expelled, the dose may be repeated several times and a thorough trial given the remedy, for it is not disagreeable to the taste and produces no unpleasant symptoms.

Turpentine may prove effective when all other remedies fail ; it is better to give it in as large a dose as can be borne than in divided doses. It may be given in emulsion with milk or in capsules.

There are various other remedies which are used, but none will be found so effective as those mentioned.

Very often when the worm is passed the head will not be found. It may easily escape observation, or the worm may break off shortly behind the head, leaving this *in situ*. It seems to make no material difference whether the head comes away or not, since the worm dies when separation takes place shortly behind this. Sometimes a large portion of the worm follows the administration of remedies, but a considerable mass is left. There then results an abatement of all the symptoms for two or three months, but they will return with a further growth of the parasite. The worm may be expelled *in toto* as a rolled-up mass, or in several sections.

ASCARIDES.—The ascaris lumbricoides is the most common parasite in children, and, next to the trichocephalus dispar, the most harmless. It is a long, cylindrical, yellowish or reddish-yellow worm, pointed at both extremities. The body is marked by four longitudinal dark bands and is striated transversely. At the head are three rounded elevations, and between these a number of fine teeth. The male is easily distinguished from the female ; it is smaller, the posterior extremity much thinner, and always curved or rolled upon itself, while the female is straight. The length of the male is from four to seven inches, and of the female from six to eleven.

The vulva is in the middle line of the body, and nearer the head than the tail. The eggs are oval in shape, 0.075 mm. long and 0.058 mm. wide; when first passed they are almost transparent, but soon become yellowish and opaque. They undergo no development within the intestine, but pass out with the fæces in great numbers. Much time is apparently required for their development, which takes place only under suitable conditions of warmth and moisture. The eggs are very indestructible, and may remain years undeveloped and then develop as soon as they are placed in favorable circumstances. The worms are much more frequent in children than in adults, and more frequent in females than in males. The embryo, still enclosed in the egg-membrane, is taken into the body in the drinking-water and in various other ways.

The essential habitat of the worm is in the small intestine, but it may wander throughout the intestine. It may pass through the rectum either with or without the fæces, or it may take an upward course and be found in the stomach, œsophagus, or nose. Cases have not infrequently been seen where it has entered the air-passages, producing death either instantly from suffocation or later from gangrene of the lung. It may also pass from the intestine into the biliary or pancreatic ducts.

Symptomatology.—The most varied symptoms are given as due to the presence of these worms. Here, as in the case of tape-worm, the only reliable information is found in the presence of either the worms themselves or their ova in the stools. It is certainly true that in most children, even when the worms are present in considerable numbers, no symptoms are produced. In other cases, generally depending on the number of worms, certain vague symptoms are caused. There may be vague and unpleasant sensations in the umbilical region, which may increase to colicky pains. Sometimes there is more or less dull continuous pain, which at times becomes more severe. The abdomen is often swollen, the appetite is capricious, and there may be nausea and vomiting. Mucous diarrhœa is sometimes present. Many of the symptoms which are much regarded by the laity, such as itching and picking at the nose, are of no importance. Children who are weakly and in whom the worms are present in great numbers may lose flesh and become pale. There are various nervous symptoms, such as grinding of the teeth, unquiet sleep, disturbance of sensation, widening of the pupils, reflex convulsions, etc., but these are most common in very young children. There have been cases reported where obstinate epileptiform hysterical convulsions similar to chorea, aphonia, disturbances of sensation, etc., have ceased after the expulsion of a number of the worms.

In the tropics not only are the worms more frequent, but the symptoms produced by them are more severe. This is due to the enormous numbers of them which are sometimes present.

It is probable that the presence of the worms may aggravate any intestinal affection, but they seem to produce absolutely no effect on the healthy mucous membrane. For a long time it was supposed that the worms could penetrate the intestine and enter the peritoneal cavity, or even wander elsewhere in the body. The evidence of this was sought in the presence of the worms in abscesses about the abdomen, and in the peritoneal cavity, either with or without peritonitis. It may be regarded as certain that they cannot pass through the intact intestinal wall, for their structure precludes this. The abscesses in which they have been found were in the inguinal or umbilical region, the most common places for hernia, and it is probable that these were produced by the parasite entering an inguinal or umbilical hernia and by its presence and movement in this confined place causing perforation with abscess-formation. When they are found in the peritoneal cavity, with peritonitis, they may have escaped through some small and easily-overlooked opening in the intestine, or in other cases some other parasite may have been mistaken for the ascaris.

It is always serious when the worm ascends the intestine to the pharynx and enters the larynx. It produces severe paroxysms of coughing, a feeling of suffocation, pain in the region of the larynx, and frequently a quickly-fatal asphyxia. If it passes the larynx and enters the trachea the symptoms become milder. There are still violent cough, hoarseness or even aphonia, pain in the breast, vomiting, and convulsions. If it is not expelled by the fits of coughing, death takes place in from one to three days, generally from gangrene of the lungs. It is a not very uncommon thing at autopsies to find a worm in the pharynx or the larynx, it having crawled there after the death of the individual.

Diagnosis.—As we have said, there are no symptoms which are in any degree positive. We may suspect the presence of the worms from a group of symptoms, but the diagnosis must always be made from finding the worms or the eggs in the fæces. The eggs are often present in extraordinary numbers, and can be easily recognized. In a piece of fæces no larger than a grain of wheat Davaine found from three hundred and twenty to three thousand eggs. In this case twenty-two worms were expelled after the administration of santonin, and thirteen of the twenty-two were females. The eggs of the lumbricoid can easily be distinguished from the long-pointed eggs of the oxyuris vermicularis and from the round eggs of the tænia. In looking for the eggs it is best to give a purgative, then filter the liquid stools and examine the solid residue microscopically.

Prognosis.—The prognosis is favorable. Unless the parasites are in enormous numbers they do not produce any dangerous conditions; but there is always some danger that they may wander into some other part and produce suffocation by entering the air-passages, or set up a purulent hepatitis by entering the bile-duct.

Treatment.—The remedy on which the most reliance can be placed is santonin, and this has the further advantage of being almost devoid of taste and smell. It may be given mixed with a little sugar in doses of from one-fourth to one grain. Sometimes it may be given mixed with a little calomel, and should then be followed by a purgative. The worms generally begin to come away on the second day, and they may continue to pass for several days longer. As long as the worms continue to pass, the treatment should be continued; but the single dose should not exceed one grain.

PIN-WORMS.—The oxyuris vermicularis, commonly known as the seat- or pin-worm, though not so common as the ascaris lumbricoides, produces much more unpleasant symptoms. The male is much smaller than the female, and has the tail rolled into a spiral. The length of the male is from one-twelfth to one-sixth of an inch, that of the female from one-fourth to one-half of an inch. In both sexes the body presents a more or less fusiform shape, the anterior end being rounded to form a somewhat abruptly truncated head, which is rendered very conspicuous by a bulging of the transparent integument around the mouth, which presents in profile the appearance of winged appendages. The integument is transversely striated and of silvery whiteness.

The eggs are smooth, oval, 0.053 mm. in their long diameter and 0.028 mm. in their short; they undergo segmentation while in the intestine, and when discharged a tadpole-like body is often found within them. When they are placed in warm water this tadpole-like embryo soon changes into a long slender worm and leaves the egg.

The whole course of development takes place in the intestine. As soon as the worm is freed from the egg it wanders into the upper part of the intestine. Here it grows quickly, the sexes become differentiated, and after this it descends again into the lower portion of the small intestine, where conception is effected. The females then enter the cæcum accompanied by the males, and here and in the large intestine complete development takes place. The eggs are deposited in the rectum, partly in the mucus and partly on the mucous membrane. The development of the worm is very rapid. Leuckart and three of his scholars swallowed the eggs, and found the young embryos in the stools fifteen days afterwards.

The worms are also propagated by self-infection. They get on the fingers or beneath the nails, from the efforts which the patient makes to allay the intolerable itching in the neighborhood of the anus, and are conveyed in this manner into the mouth. Cobbold mentions the case of a person afflicted with myriads of these entozoa who in his distress and rage was accustomed to catch the worms and bite them in two. As he did not select the male worms for this pleasant operation, he exposed himself to a terrible revenge, for no surer way could be found to introduce the eggs into the intestinal canal. It will readily be seen that this method of self-infection must play a greater *rôle* in children than in adults, owing to the fact that their habits are less cleanly.

The worms may exist in large numbers, and their capacity for increase is very great. On this account the disease is often very obstinate: although great numbers may be expelled, their place is quickly supplied if any worms remain.

Symptomatology.—They may be present in considerable numbers without producing any symptoms. Ordinarily they produce a chronic irritation of the rectum, with itching, burning, and pain which extend to the external genitals. In the evening and at night, especially after the patient has become warm in bed, the worms seem to be in their most excitable condition and give rise to various unpleasant symptoms. Frequently the symptoms return every night with the utmost regularity. In children, especially, various sympathetic nervous phenomena may be added, such as restlessness, itching of the nose, involuntary twitchings, grinding of the teeth during sleep, chorea, convulsions, and even epileptiform seizures. The itching and burning of the genitals may lead in both sexes to onanism. In young female children pruritus and leucorrhœa are sometimes seen, and in those approaching the age of puberty, various forms of hysteria. There is often a marked anæmia, but instead of anorexia there may be a ravenous appetite, especially in children. Diarrhœa is sometimes present, but there may be considerable constipation. If the condition has lasted a long time the stools are rather soft, of a very fetid odor, and mixed with mucus. Not only do the worms pass out in the stools, but they also creep out spontaneously, and an investigation of the anal region will often reveal them in the folds around the anus. In female children they may enter the vagina and here set up a purulent inflammation. Within the anus the mucous membrane is swollen, deeply injected, and covered with mucus, which is often tinged with blood.

Diagnosis.—The diagnosis is generally easy to make. On inspection of the anal region the worms will often be seen, though they are so small that they can easily elude observation. By washing out the rectum with cold water and examining this they may always be found if present. The eggs may be recognized on microscopical examination by their long-oval form. There are various conditions other than the worms which can produce the local symptoms, and the only certain basis for diagnosis here, as in the case of other worms, is the presence of the worms or their eggs.

Prognosis.—There are no really dangerous conditions produced by the oxyuris, but the condition is unpleasant and often very difficult to treat successfully. They may apparently all be driven out, but if a few remain in the folds around the anus these will serve as new foci for further infection.

Treatment.—In this disease, which is so obstinate and which often returns after apparent cure, it is necessary not only to treat promptly, but also to continue the treatment for some time. The chief reliance in the treatment has been wrongly placed on injections which have for their purpose the destruction of the worms in the rectum. Although the unpleasant symptoms which we have described are almost entirely due to the presence of the worms in the rectum, it must not be forgotten that the worms here are constantly being added to from the small intestine. It is best to add internal medication to the rectal injections, and thus attack the worms from above and below. The internal treatment is the same as that for the lumbricoid worms. Various ointments may be rubbed into and around the anus to destroy the worms which are in the folds. Rectal injections, either of cold water alone or of a weak solution of quinine, may be used with good effect. Injections of a solution of corrosive sublimate, one to one thousand, have been recommended. The treatment should be continued at intervals for several weeks, until both the worms and the eggs have disappeared from the stools. During the treatment care should be taken that the digestion is not impaired. The necessity for the utmost care in the treatment will become apparent when it is borne in mind that the disease in adults and old people sometimes seems incurable.

TRICHOCEPHALUS.—Another parasite which is exceedingly common, but whose presence in the intestine produces few or no symptoms, is the trichocephalus dispar. The peculiarity of this parasite consists in the anterior part of the body being exceedingly thin while the posterior part is thicker. The male is shorter than the female. The length of the male worm is from one and one-fourth to one and a half inches, while that of the female is two inches. The eggs are oval, and somewhat resemble those of the oxyuris, but are not so sharp-pointed. The habitat of the parasite is in the cæcum, and it is seldom found in any other part of the intestinal canal. When great numbers of them are present they may produce some irritation.

TRICHINÆ.—The most dangerous of the worm-parasites are the trichinæ, but the real danger with them is not connected with the presence of the adult worm in the intestinal canal, but with the embryonic condition in which the parasites invade the voluntary muscles. The embryos are frequent in the muscles of pigs, and from eating flesh containing them, in an imperfectly-cooked or a raw condition, infection takes place in man. They may also be found in other animals,—in rats, cats, mice, moles, and some others. The infection of the pig results principally from eating the flesh of infected rats and mice. The embryo worms are coiled up in the muscular fibre, and are $\frac{1}{28}$ of an inch long and $\frac{1}{620}$ of an inch broad. When introduced into the stomach they increase in size and become sexually mature in two or three days. They produce viviparously an astonishing number of young, estimated by various authors at from two hundred to one thousand. These penetrate the mucous membrane, and in a short time find their way to the different muscles of the body.

Symptomatology.—The presence of the sexually-mature trichinæ in the intestine produces a more or less intense gastro-intestinal catarrh: even small ulcers and erosions in the duodenum may be caused by them. Secondarily the mesenteric glands are swollen and hyperæmic. When the embryos first enter the muscles they cause the most exquisite myositis, with a great deal of small-cell infiltration. They then enter the single muscular fibres, roll up into a spiral, and become surrounded by a capsule, which is at first soft, then calcified.

The symptoms are divided into two groups,—those caused by the worms in the intestinal canal, and those caused by the invasion of the muscles.

Those in the intestine are due principally to the perforations of the wall. When it is considered that the number of these perforations may reach into the millions, it can easily be seen that notable disturbances may be produced. These are shown by diarrhœa, abdominal pains, and vomiting. There are usually loss of appetite, general malaise, weakness, headache, and unquiet sleep. The secondary symptoms relate to the muscles. The chief symptoms are intense pain and inability to move. Constitutional symptoms accompany both conditions, and often simulate those of typhoid fever. Œdema of the face or of the lower extremities is often seen. Death takes place from exhaustion, and is often preceded by coma.

Prognosis.—The prognosis depends almost entirely on the number of embryos which are generated in the intestinal canal. When a great number are present, the disease is almost necessarily fatal. If not fatal, the symptoms slowly subside, the worms in the muscles become encysted, and thenceforth they are quiescent.

Treatment.—The only time when treatment is of any efficacy is when the mature worms are in the intestinal canal. Then purgatives and anthelmintics are indicated. In the very beginning of the attack emetics may do good. Afterwards, in spite of the diarrhœa, purgatives should be freely given. Calomel in rather large doses should be given every three or four days, followed by full doses of castor oil. Injections of corrosive sublimate, one to two thousand, may also be given. Benzine, given both by the mouth and as a rectal injection, has been recommended. After the worms have left the intestine no medication directed to their destruction is of any avail, and the general condition alone can be treated.

The prevention of the disease is as easy as its cure is difficult. Thorough cooking of the meat, by which all parts of it are raised to the boiling-point, is all that is required. Other modes of preparation of the meat, such as prolonged smoking, pickling, etc., have no effect on the parasites.

HERNIA IN CHILDREN.

By WILLIAM J. TAYLOR, M.D.

HERNIA in children may be either *congenital* or *acquired*. Of congenital hernia we have *inguinal*, the most common; *umbilical*, rarely seen in later childhood; and *diaphragmatic*. Acquired herniæ are not common: they may be either *femoral*, which is never congenital; *inguinal;* or through the *linea alba*, not truly umbilical.

A hernia is a protrusion of a portion or the whole of a viscus through the walls of the cavity in which it is contained. The term is generally used to designate a protrusion of the abdominal contents through one or more of the natural openings. These protrusions or herniæ are named, according to their position, *umbilical*, *inguinal*, *femoral*, etc.

The cause of hernia in the umbilical and inguinal varieties, with which we have most to do, is an arrest of development in the fœtus. The inguinal variety is due to a delay in the descent of the testicle and to the incomplete formation of the transversalis, internal oblique, and cremaster muscles. At the umbilicus the closure of the opening is delayed by the omphalo-mesenteric vessels which emerge here.

The crying of the new-born child and distention of the intestine from food improperly digested may force out a portion of the bowel through one or other of these imperfectly-closed openings. A weakened condition of the inguinal and umbilical rings may persist for months and even years, and it is not until some special effort is made, as in crying, straining, or vomiting, that the weakened ring dilates and a hernial protrusion occurs.

The femoral variety is extremely rare before puberty, and is never congenital, but always acquired. In a case reported by Mr. Thomas Bryant[1] it showed itself first after violent jumping in a girl aged nine years whose muscles were all much relaxed from poor health.

There are certain general signs common to all herniæ. More or less suddenly, near some one or more of the natural openings there will appear a tumor, which increases in size on muscular effort or straining and gives an impulse to the finger on coughing. It generally disappears on lying down. The tumor, if of intestine, will be elastic, and, when firmly grasped and manipulated or reduced, a gurgling, due to the gases in the interior of the intestine, may be noticed.

---

[1] Medical Times and Gazette, 1862, vol. i. p. 136.

Herniæ in children nearly always consist of intestine, and in extreme cases the greater part of the bowels may be so displaced. The omentum is so poorly developed that it forms little or no part in such ruptures. By gentle manipulation this tumor can be replaced within the abdominal cavity. Of course if there be strangulation this cannot be done.

Herniæ may be single, double, or multiple.

CONGENITAL UMBILICAL HERNIA.

In early fœtal life the abdominal cavity is open in front, and is closed by a gradual development of the abdominal plates. The last point to close is the umbilicus, where the omphalo-mesenteric and allantoid vessels pass. Sometimes, as in other parts of the body (*e.g.*, spina bifida, hare-lip, and similar deformities), the two sides coalesce normally except at the final point of closure, where the process is arrested. If this is at the umbilicus it is left patent, and readily affords exit to the abdominal contents.

Dr. James R. Chadwick, of Boston,[1] suggests a second factor. The intestines are developed outside of the abdomen. If the volume of the intestines be too great to be easily enclosed by the undersized abdominal walls at a time when the latter should be normally closed, intra-abdominal pressure will prevent the retreat within the abdominal cavity of certain portions of the intestines which have until that time lain normally in the umbilical cord. When the umbilical vesicle and its duct with their vessels fail to atrophy in the process of embryonic growth and persist to a later period than usual, they act as a cord anchoring that portion of the intestine with which they are connected, outside of the umbilical ring, thus producing the hernia. This latter condition may occur without there being any deficiency in the development of the abdominal plates. He demonstrates this by some dissections.

A case reported by Dr. T. R. Ronaldson[2] seems to confirm Chadwick's view. In this case, at birth, a child was found to have a tube of skin, from two to three inches long and two inches in diameter, projecting downward and forward from the region of the navel. At the end of the tube, and below, sprang the umbilical cord. The end of the tube consisted mainly of a unilateral bulging in the umbilical cord. On the upper surface was a tumor the size of a large apple. The covering of the tumor was composed simply of amnion; the contents consisted of a portion of the liver and numerous coils of intestine, which could be plainly seen through the transparent peritoneal and amniotic covering. An operation was performed, and the child recovered.

---

[1] Rare Forms of Umbilical Hernia in the Fœtus, Transactions of the American Gynæcological Society, 1876, p. 364.

[2] Edinburgh Obstetrical Society Reports, 1882–3, viii. 1017.

Dr. J. M. Barton[1] reports the case of a female child who at birth had an umbilical tumor two and a half inches high, over three inches in diameter, and slightly pedunculated. It was composed of omentum and intestine, which protruded through an opening in the abdominal wall more than two inches in diameter, and was covered by a thin layer of the expanded gelatinous matter of the umbilical cord; this was as transparent as glass. The intestine and omentum could be distinctly seen through it, and after the return of the tumor into the abdominal cavity the left lobe of the liver could be easily recognized. The cord joined the tumor about half an inch to the left of its apex, and the vessels of the cord could be traced down the left side of the tumor and entering the abdominal cavity. He operated when the child was thirty-three hours old, as the parents would not until then consent. The gelatinous covering readily broke down under the fingers and was very offensive; this was dissected away. The bowels were found to be highly inflamed; over half an ounce of opaque serum, with flakes of lymph floating in it, ran out from the abdominal cavity. The edges of the opening, measuring six and a quarter inches in circumference, were freshened and brought together with hare-lip pins, leaving an inch of the wound ununited for drainage, through which passed the umbilical vessels. The child made a good recovery.

The umbilical aperture, always open at birth, but usually closing soon after the ligation of the umbilical cord, may persist for weeks, and is covered with skin, superficial fascia, and peritoneum. A coil of intestine may readily push itself out, and it has even protruded so far as to be included in the ligature of the cord.

During the whole of the first year of life the linea alba is weak, and sudden efforts of violent coughing, straining, or crying may push a coil of intestine through some point which is weakest. This is not truly an umbilical hernia, as a rule, and is generally above the umbilicus. Holmes[2] calls it a "hernia through the linea alba." He likewise says he has never known of such a hernial protrusion between the umbilicus and the pubes.

Diagnosis.—The diagnosis of this condition is unmistakable. The position and character of the tumor, its elastic feel, the ease with which it can be returned within the abdominal cavity, the increased bulk and tension on crying or straining,—all these make the diagnosis easy. It is to be distinguished from dropsy of the funis, malignant tumors of the umbilicus, and cysts; but the differential diagnosis is so clear that it need not be elaborated.

Prognosis and Treatment.—The prognosis is always good. Even if let alone, congenital umbilical herniæ nearly always get well of themselves, for this condition persisting in late childhood is very rare. Much, however, can be done by properly-directed treatment to hasten and aid nature in her efforts at cure.

Generally a simple binder, or, better still, a disk of bone or metal from one to one and a half inches in diameter, covered with soft linen, placed over the umbilical opening and fastened there with adhesive plaster, will be sufficient. The old practice of putting a ball or a conical pad over the ring is a great mistake, as, by pressing into and dilating the ring, the very object for which the binder is applied is defeated.

---

[1] Medical News, August 3, 1889, p. 137.

[2] Surgical Treatment of Children's Diseases, p. 560.

The instrument-makers now sell a most useful apparatus made of india-rubber. It consists of a band with eyelet-holes at the ends, through which a string can be run to permit of lacing lightly to the body. In the centre of this band, which is some two inches wide, is a little bag to which is attached a bit of rubber tubing. This when inflated makes a cushion about an inch and three-quarters in diameter, and covers over but does not press into the open umbilical ring.

Occasionally all efforts by these simple measures are insufficient, and then a truss with a flat pad and a light spring must be used. Mr. John Wood[1] recommends a pad consisting of a ring over which is stretched a thick rubber diaphragm, as best for the purpose. Great care on the part of the child's nurse is needed in keeping the gut retained by the fingers whenever the binder or truss is removed, as it should be at least twice a day for purposes of cleanliness. For every time the gut comes down the ring is dilated and its closure retarded. Too great stress cannot be laid upon the importance of this care on the part of the nurse to prevent the hernia from reappearing even once, and also upon extreme cleanliness. The parts should be dusted with some simple powder every time the truss is removed, to preserve the skin from irritation.

It is also of great importance that digestion be properly performed, and no undue amount of gaseous distention of the intestines permitted, which by internal pressure might defeat our object.

Sometimes all our efforts are of no avail in retaining the gut in place, and a question of operative interference then presents itself. Nature will do much in this condition if left to herself, but still more if intelligent aid be given,—as is shown by the fact that this condition is almost never seen in late childhood. Persistent efforts, first with one and then another binder or truss, should be made before any more radical measure is attempted. Sometimes it may be necessary to keep the child lying on its back day and night, gravity thus aiding the binder or truss.

Mr. Holmes considers the best and safest method of radical cure to be a subcutaneous silver ligature introduced around the umbilical ring and including in it the pillars of the ring, the ligature cut off and allowed to remain. Acquired herniæ should be treated in the same general way as the congenital.

A case is reported by Dr. Phœnomenon[2] of successful laparotomy for umbilical hernia in a child but one hour old. The child was born with a large umbilical hernia, and, within an hour after the ligation of the cord, was placed under the influence of chloroform and operated upon. The sac, peritoneum, and wound were sutured, the abdominal cavity was sterilized, and the child made a rapid and uncomplicated recovery.

It would seem, in view of this case, which is remarkable, and of other laparotomies for umbilical hernia in children, that we should be justified, in cases of great persistency, in opening the belly, freshening the edges of the umbilical ring, and closing it with sutures. Such an operation should be done under the strictest aseptic precautions.

[2] Revue Gén. de Clin. et de Thér., July 11, 1889.

CONGENITAL INGUINAL HERNIA.

This occurs in both sexes. While very common in girls, it is in them simply the passage of the gut down a patulous canal of Nuck, and need cause little uneasiness as to final cure unless there is associated a hernia of the ovary, when the matter assumes a more serious aspect. When an ovary has made its way down this patulous canal of Nuck, as it sometimes does, it should be reduced and returned within the abdominal cavity by taxis; or, if this is not possible, an operation must be done, the canal opened, and the ovary returned within the abdomen or removed, as may be found best. The treatment for such hernia in girls when the ovary is not in the hernia is the same as for hernia in boys.

Mr. Bilton Pollard[1] reports the case of a female child aged three months, who was admitted into the Northeastern Hospital for Children under his care. One month before this the child's mother first noticed a lump in its right groin, which would at times vary in size or disappear. A truss was applied March 19, 1889, and the hernia was supposed to have been reduced. On the 27th the truss was removed, and an irreducible swelling was noticed in the right groin. The child was admitted into the hospital on the 30th. There had been some vomiting, but her bowels had moved on the morning of the 30th, and a swelling rather larger than a pigeon's egg was situated over the right external abdominal ring, and distended the upper part of the right labium majus. The skin over it was red and hot; the swelling felt elastic, and distinct fluctuation could be made out; it was irreducible, gave a dull note on percussion, and altogether simulated an abscess.

The child was placed under the influence of chloroform. The superficial tissues were œdematous and matted together. The sac was opened, giving escape to some turbid blood-stained fluid. It contained an ovary and the fimbriated extremity of the Fallopian tube; they were both greatly swollen, black or gray in color, and in places coated with lymph. The pedicle was drawn down, transfixed, and tied with silk ligatures, and the ovary and tube were removed. The child made a complete recovery, and was discharged from the hospital, cured, on the eighteenth day from the operation.

Inguinal hernia in boys is of serious moment, and, although all congenital herniæ have a tendency to natural cure, unless care be exercised in the management much trouble may result.

In the fœtus in utero the testicles are in the lumbar region, behind and partly invested by the peritoneum. As the testicle descends, which usually occurs shortly before birth, but may not take place until some time thereafter, it is accompanied by a prolongation of this serous membrane down into the scrotum. This forms the vaginal or funicular process of the peritoneum. It lies in front of the testicle and spermatic cord, and extends from the internal abdominal or inguinal ring to the lowest part of the testicle, where it forms a cul-de-sac.

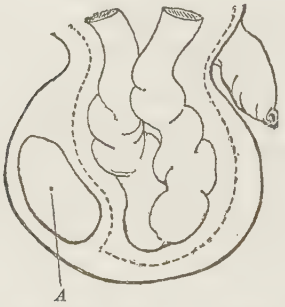
---

[1] Lancet, 1889, ii. 165.

Normally this process of the peritoneum contracts a little above the head of the epididymis and finally forms two cavities,—the superior, now called the *tunica vaginalis propria funiculi*, lying in front of the spermatic cord, and the inferior, or *tunica vaginalis propria testis*, which lies in front of the testis and lower part of the cord. The inferior cavity thus becomes and remains a closed serous sac. The superior cavity usually is obliterated by adhesion of its walls, the upper, funnel-shaped end being the "infundibular fascia" at the internal ring.

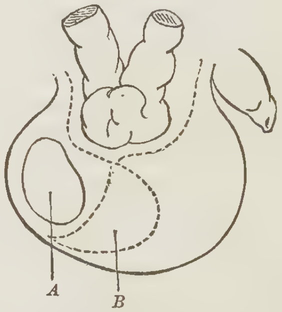
In the majority of infants some portion of the upper part of this process of the peritoneum remains open at birth, and any effort, such as crying, coughing, or straining at stool, may press a small bit of gut into the abdominal opening. As it has a ready-made serous-lined sac, it pushes down still farther, and, if the closure at the head of the epididymis has not occurred, it finds its way down into the scrotum, in front of the spermatic cord and testes. This is what is known as the *hernia congenita* of Haller (Fig. 1). It is that form which is most frequently met with, and may be found either at birth or not until weeks or months thereafter.

Fig. 1.



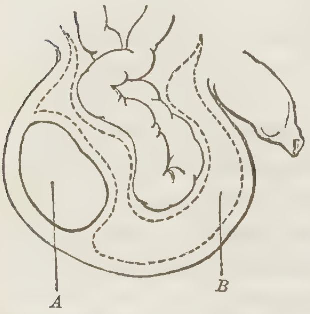
Congenital Hernia.—*A*, testicle.

Fig. 2.



Funicular Hernia.—*A*, testicle; *B*, tunica vaginalis testis.

Fig. 3.



Encysted Hernia.—*A*, testicle; *B*, tunica vaginalis testis.

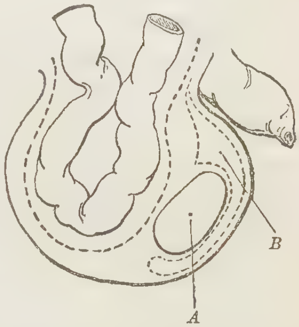
In *funicular hernia* the adhesion has formed just above the testicle, and the bowel extends only into the vaginal process of the peritoneum in front of the cord, and does not pass down into the tunica vaginalis testis (Fig. 2). With it may be associated a congenital hydrocele. In that case the hydrocele is developed in the closed inferior sac in front of the testicle as usual, and the bowel extends only a short distance down the funicular process.

In *infantile* or *encysted hernia* the tubular process has been obliterated at the internal abdominal opening or ring, while the closing process above the testicle has not taken place (Fig. 3). In the efforts of crying or coughing a loop of intestine is forced down, carrying a special prolongation of the parietal peritoneum with it, which forms a sac; this is forced down into the funicular process or tunica vaginalis. This form of hernia can be recognized only upon operating.

Mr. Edmond Owen[1] describes yet another variety, in which, the funicular process being closed at the abdominal ring but open into the tunica vaginalis testis, a bit of gut in a special sac is driven down into the scrotum behind the funicular process and tunica vaginalis (Fig. 4). In operating for this condition three layers of peritoneum must be cut through before the contents of the hernial sac are exposed.

An inherited predisposition to hernia is very common, equally so in both sexes, and is manifested in the most marked degree in infants under twelve months of age. Mr. Kingdon,[2] in speaking of this hereditary predisposition, says that fathers who themselves had hernia in infancy but who have grown out of the affection beget children with congenital hernia, who also grow out of it. Brothers sometimes become ruptured about the same age, and before their father. He states that it is not uncommon for children to be brought to the City of London Truss Society with herniæ in whom no family tendency can at the time be traced, but at their next visit, a year or so later, it will be said, in answer to the customary questions, that the father became the subject of hernia in the interim.

FIG. 4.



FUNICULAR HERNIA, WHERE THE PROCESS HAS CLOSED AT THE ABDOMINAL RING.—*A*, testicle; *B*, tunica vaginalis testis.

Race has also much to do in this affection. Lascars seldom have hernia; it is not so frequent among the Irish as among the Germans and English; and the Jews are very prone to rupture. An abnormally long mesentery is generally considered to be an important factor in the causation of hernia. If this is so, it is hard to explain why congenital herniæ are so extremely rare among monkeys. Mr. J. Hutchinson, Jr., in the course of some remarks made at a meeting of the Pathological Society of London, November 15, 1887,[3] stated that he had never met with a hernia in a monkey, a long mesentery, however, being very common. Mr. Bland Sutton, at the same meeting, said that in a dissection of over eight hundred monkeys he had found only two congenital herniæ; and if a patulous funicular process predisposes to hernia this should be common, for, with the exception of the gorilla and some of the chimpanzees, man is the only animal in which the funicular process becomes normally obliterated above the testes.

Sex.—Mr. Birkett[4] remarks that, "after carefully considering the statements of writers in relation to the numerical proportion in which the two sexes are subject to hernia, we must admit that we have not the requisite data to enable us to arrive at any satisfactory conclusion." He gives Mr. Kingdon's estimate from the statistics of the City of London Truss Society, covering a gross total of 96,886 applications for trusses, the proportion being two males to one female, taking all ages and including every variety of hernia. He shows, by these statistics for 1860 and 1861, that of children under five years of age there were 1409 males as against only 107 females.

---

[1] Surgical Diseases of Children.

[2] Med.-Chir. Soc. Trans., 1864, p. 311.

[3] British Medical Journal, 1887, ii. 1102.

[4] Holmes's System of Surgery, Amer. ed., 1881, p. 666.

Dr. Edward Swasey[1] states that it is a matter of statistics as well as of common observation at the Hospital for Ruptured and Crippled that female children are more prone to suffer with umbilical hernia than male. Just why this should be he can give no satisfactory explanation, but he suggests the proportionately larger funis in the female as a factor. Certain it is that in the adult female the navel is a wider and deeper depression than in the adult male. The fact is so marked that it was noticed even by the ancient artists, as may be seen on comparing the Venus de Milo or the Venus de' Medici with any antique male statue. The admitted frequency of inguinal hernia on the right side in comparison with that of the left is attributed by Swasey to the weight of the liver pushing downward and forcing the intestine into the open funicular process.

Treatment.—In young children the digestion must be carefully looked to. Vomiting from overfeeding or improper food; constipation or diarrhœa, with straining at stool; a persistent cough from bronchitis or elongated uvula, or chronic pharyngitis,—these must all be remedied. Then, also, nasal obstruction from growths or a chronic catarrh must be relieved. Likewise the constriction of a contracted and adherent prepuce must be overcome, as the straining thus caused may produce a rupture. All these causes operate to prevent nature in her efforts at repair, and by their persistence hinder or may even completely destroy all chances of cure directed solely to the hernial protrusion.

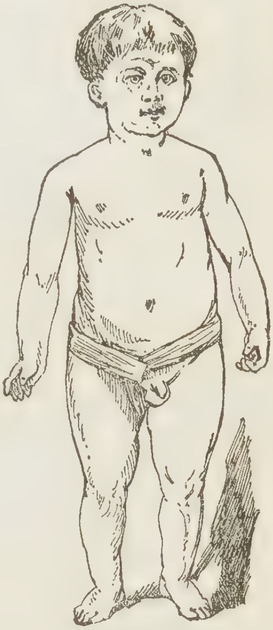
In infants and young children a truss applied to the inguinal region is often retained in place with great difficulty, and, unless the rupture be of unusual size, a very simple home-made apparatus, fully described by Mr. Walter Pye,[2] may conveniently be substituted (Fig. 5). This consists of a skein of Berlin wool—or, for very young infants with sensitive skin, of lamb's wool—made to encircle the pelvis. One end is passed through the loop of the other at a point corresponding to the inguinal ring, and may be fastened there by a thread; the free end is then carried between the thighs and is fastened behind to the portion which forms the girdle. About thirty threads are generally sufficient. This may be worn during the morning and evening bath, when a fresh, clean one can be applied. With ordinary care the skin does not become irritated, and, as the expense of such a truss is very little, since it may be washed repeatedly, it is within the reach of even the poorest. No pad is used, the bulk of the loop with the strands passed through it being sufficient. I have had a personal experience with this simple apparatus, limited to one case, and it answered admirably. I am disposed to test still further its efficacy upon the authority of so good a surgeon.

---

[1] Hernia in Children, based on a Study of Five Hundred Cases under Personal Observation, Amer. Jour. of Obstet., July, 1880, vol. xiii. No. 3.

[2] British Medical Journal, 1887, i. 1152.

FIG. 5.



Truss of Berlin wool.

Trusses are best made of a spring covered with some water-proof material, such as rubber or celluloid. The pads also should be made of hard rubber, celluloid, or hard wood, so as to be water-proof and hard. If they are made of soft material and covered with leather or chamois-skin, they become very dirty after a few days, the skin is often made sore, and, worst of all, they will not produce the pressure necessary either to keep the hernia reduced or to set up sufficient irritation to effect a cure. The spring, however, must not be too strong.

The pad which covers the inguinal ring should be slightly convex, but not so convex as is often seen, as it then presses into the already open ring, and by dilating it prevents its closing. The object should be to retain the hernia within the abdominal cavity, and to cure the hernia by exciting a local adhesive inflammation at the internal ring, thus restoring the integrity of the abdominal wall; and only pressure sufficient to accomplish this should be permitted. These being the objects, the pad should be placed over the *internal* ring, and not over the external, as we often see done. Applied at the latter place, the hernia can constantly escape into the upper part of the canal and so prevent a cure. The pad thus imperfectly applied will also press upon the pubes and cause great discomfort and local ulceration of the skin.

For children (except for umbilical hernia) the truss should always be double, as the predisposing causes always exist equally on both sides.

If the rupture be small and present only when violent efforts are made, it will merely be necessary for the child to wear the truss during the time it is out of bed. If, however, the rupture be large and persistent, then, for a time at least, the truss should be worn both day and night, to give nature an opportunity of closing the ring. In either case, whenever removed the truss should be taken off only *after* the child has lain down, and *never while erect;* and it should *always* be reapplied before the child rises, never afterwards. Omission of these precautions for a single time may undo the good of weeks of obedience to them, and even prevent a cure. Such exact care is always onerous, and in children often impossible; but it is none the less needful to insist upon it that the parents or the nurse shall give it, if we expect surely to cure so serious a disorder, which if it persists constitutes a life-long disability.

In all instances bathing with alcohol and water, or alum and whiskey, and dusting the skin night and morning with some one of the simple powders, corn-starch or violet powder, should be practised; and too much attention cannot be given to cleanliness and care in adjusting the truss.

The physician should not leave too much of the treatment in the hands of the instrument-makers, as they seldom have the requisite anatomical knowledge to guide them.

STRANGULATION.

Herniæ in children frequently become strangulated; incarceration is extremely rare, for seldom has the hernia lasted a sufficient time for the sac to become adherent to the remains of the vaginal process of the peritoneum. When strangulation does occur, immediate efforts must be made to relieve it, as delay is quite as dangerous with children as with adults.

Strangulation is a constriction at the neck of the sac sufficient to obstruct the circulation and to paralyze the nerves, as well as to arrest the passage of the contents of the bowel. The constriction may be total, and if not speedily relieved is followed by gangrene of the gut; or it may be only partial, a small portion of the bowel being constricted and a linear ulceration caused, which, if unrelieved, eventually becomes a perforation, allowing the contents of the bowel to enter the peritoneal cavity and give rise to a violent peritonitis.

Occasionally the contents escape externally through the skin, forming a fæcal fistula.

Symptoms.—The symptoms of strangulation are characteristic. There is persistent constipation. If the strangulation be slow there may be one or more stools, which unload the bowel below the constriction and are followed by constipation; but if it be sudden the constipation will be absolute.

The abdomen becomes distended; flatulent eructations occur, with colicky pains, which increase in force and are referred usually to the region around the umbilicus; vomiting soon sets in, at first of undigested food, then of chylous digesta, then of bile, and finally it becomes fæcal. The latter is due to reverse peristalsis.

The abdominal distention and tenderness increase. The temperature, which at first is normal, rises to a moderate height, but as the obstruction persists it falls below normal. The pulse at first is rapid—120—and full, but becomes thready, weak, and then intermittent. The respiration is quick, shallow, and thoracic. The urine is generally decreased in amount, but varies according to the amount of sweating, which is almost constant.

There is great restlessness; the countenance becomes pallid and sallow;

the eyes are sunken; a cadaveric smell is noticed; and the little patient dies of exhaustion.

Treatment.—When the diagnosis of strangulation is reasonably certain, no time should be wasted in palliative measures.

An anæsthetic should be at once administered and efforts at gentle taxis begun. The tumor should be grasped between the fingers and gently compressed, in order, if possible, to press out some of the gaseous contents of the bowel. Then gentle efforts should be made, in the line of the inguinal ring and canal, to replace the gut, endeavoring always to return first that part of the bowel which came out last,—that is, the portion of the bowel in the canal and next to the external ring. Taxis should always be gently done, especially if the strangulation has persisted for more than an hour. If hiccough has set in, Mr. Birkett condemns the employment of taxis, and advises immediate operation. The general condition of the child must be considered, and if it be much exhausted operate at once.

The operation is performed in children as in adults, and must always be strictly aseptic. The parts should be carefully shaved, washed with alcohol or ether, and finally thoroughly but gently scrubbed with a one to four-thousand solution of bichloride of mercury. It is not advisable to use a stronger solution than this with children, as their skin is sensitive and may be blistered by it.

An incision is then made over the tumor in the line of its greatest diameter, which will be in the line of the inguinal canal, the skin and superficial fascia gone through, and the hernial sac exposed. It is generally necessary to open the sac in children, as the constriction is nearly always at its neck. The sac will be recognized by its glistening surface and by the distribution of its blood-vessels, and should be caught up with two pairs of forceps, and a small incision made between them.

A grooved director is now introduced, and an opening made which will freely admit the introduction of a finger. The constriction in children is seldom so great as in adults, and a director can generally be pushed past the constriction, a knife passed down along it, and the edge of the neck of the sac nicked upward and inward. The finger can then usually make sufficient dilatation to enable the bowel to be replaced.

If the bowel is in good condition, and no gangrenous or ulcerated points are discovered, it may be pushed back into the abdominal cavity. If, however, there be gangrene or much ulceration, the gut must be drawn out until healthy bowel appears both above and below; sponges are then to be packed around to shut off the peritoneal cavity completely, the bowel opened, the edges stitched to the skin, and an artificial anus made.

If the gut is in a satisfactory condition, an attempt should be made to effect a radical cure by bringing together the pillars of the ring. The hernial sac being generally the funicular process of the peritoneum, nothing can be done with that beyond passing a silk suture around it, in the hope of bringing it together.

Gerster, of New York,[1] recommends that in children no attempt be made to close the external wound by means of sutures, but that the wound be packed with iodoform gauze, in the hope that if the surface be allowed to granulate, a firmer cicatrix will result than if it be left to heal by primary union.

There is often great difficulty in keeping such a wound aseptic, as the child if young passes its urine over and soils the dressing and is generally very restless.

It is, however, usually better to introduce a rubber tube and horse-hair for drainage, and suture the wound and dress it with sublimate gauze, rubber dam, and a bandage, a hole being made in the rubber dam for the penis.

Dr. Royal Whitman, of Boston,[2] recommends that the leg be flexed upon the body and securely bandaged to a bent wire frame, known as Cabot's hip-splint. This apparatus in children is of great service in preventing the child from tearing off the dressing, and the fixation of the leg aids materially in effecting a rapid cure.

The diet for the first twenty-four hours should consist of nothing but a little milk and lime-water, given at short intervals, and must be liquid in character until the wound is entirely healed.

It will be necessary for the child to wear a truss afterwards for at least six months, and possibly a year.

Dr. Frank Woodbury[3] reports an operation for strangulated inguinal hernia in a child forty-five hours old, performed by Dr. Thomas H. Andrews.

The child was delivered at 5 P.M., August 10, 1874. There was difficulty in establishing respiration. He afterwards fretted as though in pain, and the mother detected a swelling in the right groin. The next morning the tumor was the size of an orange. Taxis, repeated after a warm bath and small doses of opium, was ineffectual in reducing the rupture. A second and a third attempt at taxis failing, at the end of forty-five hours, the tumor being then the size of the child's head, ether was administered, the sac opened, and the constriction at the neck of the sac relieved by the knife and fingers. The tumor was found to contain the greater part of the small intestine. The walls of the canal were brought together with sutures, and the child made a rapid and complete recovery.

Mr. J. Lionel Stretton, of Kidderminster, reports[4] a case of operation for strangulated inguinal hernia in a boy born July 28, 1886. On August 16 a rupture made its appearance on the right side, and was reduced. On the 25th it reappeared and became strangulated. Herniotomy was done in Mr. Stretton's office, and the boy completely recovered, without a bad symptom, by September 17.

Dr. L. W. Steinbach[5] reports a case of double inguinal hernia in a male child thirty-eight days old, with strangulation on the left side.

---

[1] New York Medical Journal, January 21, 1888.

[2] Boston Medical and Surgical Journal, March 22, 1888.

[3] Philadelphia Medical Times, December 25, 1875.

[4] Lancet, 1887, vol. i. p. 1029.

[5] Medical and Surgical Reporter, January 10, 1885.

The child was born September 2, 1884, and when Dr. Steinbach saw it all the symptoms of strangulation, with fæcal vomiting, were present. Taxis was useless. On October 14 a free incision was made, the sac opened, a constriction at the neck of the sac relieved by the knife, and the bowel replaced. The ring was brought together for radical cure. Drainage and full antiseptic precautions were used. A phimosis was relieved at the same time. The wound healed, with no symptoms of peritonitis or inflammation anywhere. Death occurred, however, on the fifth day after the operation, but, Dr. S. thinks, from causes other than the hernia, as the child was weak, sickly, and jaundiced from birth.

RADICAL CURE.

In children an operation for radical cure is seldom necessary, as with care in the adjustment of the truss much can be accomplished. If the hernia be not retained by the truss, the child should be put to bed and kept on its back, as a truss which will not retain the hernia while the child is running about will frequently do so very well while it is in bed. If this is persisted in, a cure will generally be effected.

There is so much written in praise of the radical cure that we may be oversure of our results. When simple measures are so generally effective, why expose the little patient to such additional risks as all radical-cure operations necessarily involve? If, however, after persistent use of the measures just mentioned, the hernia cannot be retained, an operation must be undertaken.

For this purpose the operation of McBurney, of New York, is the best.[1]

The sac is carefully separated from the cord and opened, the gut replaced within the abdominal cavity, and a ligature of silk thrown around the sac as high up as possible, care being taken to keep the finger well inside the sac while the ligature is being tightened, to prevent the possibility of including the gut within the ligature. The sac is then cut away, and the stump is transfixed with a needle armed with a stout silk ligature and is stitched into the ring. Deep sutures of relaxation are then introduced to bring down and partially invest the sides of the wound, but not to close it. The incision in the scrotum is now sutured, and the wound over the ring packed with iodoform gauze and allowed to heal by granulation.

As the wound is an open one, drainage is perfectly free and the resulting cicatrix is very firm. After six weeks in bed the patient is allowed to get up and begin to go about without a truss.

FEMORAL HERNIA.

Femoral hernia is extremely rare before the age of puberty, and is never congenital. Swasey (*loc. cit.*) reports the following extraordinary case:

A boy aged sixteen years presented himself at the hospital with unmistakable double femoral hernia, with the following history, which was given by his mother in such a distinct and careful manner that little doubt can be felt as to the truth of it. He had when one year old a bad bronchial affection, with severe cough, and during this time the tumors appeared. They would disappear on lying down, and increase in size on standing up, and especially upon coughing. The boy said the lumps had been present as long as he could remember.

---

[1] New York Medical Record, March 23, 1889.

Dr. Swasey mentions also another case, a girl twelve years of age, whose mother positively asserted that the swelling had been present for four years.

Mr. Thomas Bryant[1] reports two cases, both girls, aged nine and twelve years respectively. In both instances the herniæ were the direct result of violent exertion. A truss completely relieved them.

The rarity of femoral hernia in children is due to the anatomical relation of the parts. The points of attachment of Poupart's ligament, the spine of the pubes and the anterior superior spine of the ilium, are comparatively near together during childhood, as the pelvis has not attained its full growth, and the space between the ligament and the border of the bony pelvis is so slight that it is difficult for the gut to push its way through the femoral opening. The muscles, the iliacus and the psoas, are well developed, and, with the vessels, completely fill the space.

When it does occur, it is generally in children of poor muscular fibre and debilitated from long illness or great poverty, with its accompanying loss of tone and muscular wasting.

The diagnosis is not difficult. A tumor appears suddenly in the groin, below Poupart's ligament and directly over the saphenous opening. The tumor is elastic, resonant, can be generally returned without difficulty into the abdominal cavity, and has the gurgling characteristic of all herniæ. It increases in size when the patient is standing erect, and gives an impulse on coughing.

The treatment must be directed to returning and retaining within the abdominal cavity the protruded gut with its sac. This can best be done by a properly-fitting truss, of the same material as those already recommended for the inguinal varieties of hernia, but slightly modified as to form. Femoral hernia in children might become strangulated, and, if so, the administration of an anæsthetic and taxis would be required. If taxis fail, herniotomy must be performed, and differs in no particular from such an operation performed upon an adult.

DIAPHRAGMATIC HERNIA.

Diaphragmatic hernia is an extremely rare condition, and may be either congenital, which is by far the most common form, or traumatic.

The symptoms are pain and dyspnœa, and by auscultation the movements of the intestinal gases may be heard within the chest-cavity. If traumatic, there may be acute internal strangulation.

Dr. Henry J. Bowditch, of Boston,[2] reports several cases of diaphragmatic hernia as congenital in children. One was a young man of seventeen, with complete absence of diaphragm on the left side. The pleura contained the stomach, the major part of the colon, and several loops of small intestine. One case was four years of age, and one was seven years.

---

[1] Medical Times and Gazette, 1862, vol. i. p. 136.

[2] Buffalo Medical Journal, 1853.

Nothing can be done in the way of treatment in the congenital variety. In the traumatic, if there are symptoms of strangulation, laparotomy or opening the chest and suture of the diaphragmatic opening, as in the unique case of O'Dwyer,[1] give the only possible chance to aid the little sufferer.

LUMBAR HERNIA.

Mr. Edmond Owen[2] reports the case of a girl aged five and a half years, who about a year before he saw her had fallen down-stairs and injured her back. An abscess formed and opened spontaneously above the left hip-bone, leaving for a long time a sinus, through which pus was discharged. Some months after the sinus healed, a painless swelling appeared at the seat of the old sinus. This swelling was about the size of a small orange, and was just above the left iliac crest, in the interval between the anterior border of the latissimus dorsi and the posterior border of the external oblique muscles,—the triangle of Petit. This swelling was resonant, and its contents could be completely returned within the abdominal cavity; it slipped back spontaneously when the child lay on the right side. A clearly-defined abnormal aperture, as large as the end of a man's thumb, could be demonstrated. A cough would at once drive the bowel again into the sac: it was probably a portion of the colon, as hardened masses, supposed to be fæces, could be felt within it. He performed an operation for radical cure, by making an incision down to what he supposed to be the transversalis fascia, thrusting back the sac and its contents within the abdominal cavity, and approximated the edges of the latissimus dorsi and external oblique muscles by deep sutures. The child made a complete recovery.

Mr. J. Hutchinson, Jr.,[3] in a paper on lumbar hernia, mentions four other cases occurring in children. Two were congenital, and in one of these the tumor was supposed to be a lipoma; one followed directly after a fall; and another followed the healing of a spinal abscess.

The diagnosis is not difficult; but the tumor has been mistaken for an abscess, incised, the gut opened, and a fæcal fistula resulted. The absence of true fluctuation, with the resonance on percussion and the facility with which the contents of the swelling can be returned within the abdominal cavity and its increase in bulk on coughing, should prevent such a mistake; and, although the condition is very rare, the possibility of such an occurrence must be borne in mind.

The treatment should consist in the application of a well-fitting abdominal belt to retain the hernial protrusion, and generally this is sufficient. Mr. Owen, in the case just mentioned, was the first to perform an operation for the radical cure of the condition, and his plan should be tried if the simpler means fail.

The following curious—and, I believe, unique—case is reported by Dr. W. T. Wilkins, of Kansas:[4]

[1] New York Medical Record, October 12, 1889.

[2] British Medical Journal, 1888, i. 957.

[3] Ibid., 1889, ii. 71.

[4] St. Louis Medical and Surgical Journal, June, 1888, p. 340.

During a violent wind-storm a young woman in the eighth month of pregnancy was made insensible by being struck in the abdomen by the corner of a table.

Labor set in on the following day, and she was delivered of a male child with a peculiar "hunch on its back." Dr. Wilkins saw the child on the sixth day after delivery, and found the "hunch" of a purple color and about the size of a goose-egg. He diagnosticated a hernia at the juncture of the last dorsal with the first lumbar vertebra, and operated on the following day.

A longitudinal incision about four inches long was made over the hernial sac, when it was found that the vertebræ were separated to the extent of half an inch. Through this separation protruded the hernia. The spinal cord had been pushed to one side. The hernia was returned without opening the sac, the cord carefully replaced, and the vertebræ brought into exact apposition. To keep the bones in place, a carbolized silk ligature was passed through the superior intervertebral notch of the dorsal vertebra, into the superior intervertebral notch of the lumbar vertebra, through the inferior intervertebral notch of the lumbar, back on the opposite side through the superior intervertebral notch of the dorsal vertebra, repeating this three times, and making a figure-of-eight knot binding the bones firmly in position. The external wound was closed with catgut sutures, the whole dusted with iodoform, and the dressing finished with a broad rubber bandage. Antiseptic precautions were observed throughout the operation, which lasted about half an hour. The wound healed by first intention, and the child was practically well in six days.

Mr. T. Holmes reports[1] the case of a female child aged three years, in whom a tumor protruded behind the labia minora, between the urethra and the vagina, clearly an extension of the vesico-vaginal pouch of the peritoneum.

It contained intestine, which was very easily reduced, leaving a distinct ring where it had protruded. As the tumor increased in size, he reduced the hernia into the belly, dissected flaps of mucous membrane off each side of the vagina, and united the parts around the ring by numerous sutures. Union took place by granulation and contracted the ring, and a cure, at least for the time the child was under observation, was effected.

INTESTINAL OBSTRUCTION IN CHILDREN.

By W. W. KEEN, M.D.

INTESTINAL OBSTRUCTION is a mechanical impediment to the passage of the contents of the intestinal canal. For clinical purposes it is usual to divide the causes into three classes,—*acute, subacute*, and *chronic*. An acute obstruction may become subacute or chronic, and a chronic case may become acute. It is, therefore, sometimes difficult to determine accurately the condition we have to deal with, for one form may take on a few or many of the symptoms of the other. Mr. Fred. Treves[1] describes yet another class, which he calls *ultra-acute:* here the symptoms are so severe that death occurs within a few hours, and we are powerless to aid.

In acute cases the attack is always sudden, the symptoms are violent, and the diagnosis is frequently difficult. The prognosis is always grave, for, unless the cause of the obstruction be removed and immediate relief be had, death will speedily ensue.

Subacute obstruction has many of the symptoms of both the acute and the chronic condition. The attack is not so sudden, neither is it so violent, while the demand for relief is not so urgent, and the obstruction may assume a chronic form.

Chronic obstruction, on the other hand, comes on more slowly, the symptoms are not so urgent, nor is the danger of death so imminent. Chronic obstruction may even be spontaneously relieved.

The most common causes of acute obstruction are congenital malformations, such as imperforate anus, absence of rectum, and atresia of the intestine due to fœtal peritonitis. As these conditions are fully discussed in another place in this volume, they need only be mentioned here.

Of other causes of intestinal obstruction the most common are foreign bodies, volvulus, intussusception, and constrictions due to bands and other similar mechanical causes. These will now be considered in the order named.

FOREIGN BODIES.

Either accidentally or intentionally, children frequently swallow foreign bodies, which by their presence within the intestinal canal cause obstruction. They act either by their bulk, mechanically obstructing the lumen of the gut, or by the irritation that they produce, which causes inflammatory swelling of the intestinal wall and finally obstruction. The variety of these foreign bodies swallowed by children is very great, and it is wonderful how many and how large in bulk some of them are,—fruit-seed, cherry-stones, marbles, bullets, coins of all sizes, needles, cocoa-nut fibre, wool, and, in fact, almost anything which it is possible for them to get into their mouths. Sometimes nature is overtaxed and does not permit the foreign substances to pass per anum, as they generally succeed in doing, and they become lodged in some portion of the gut, when in a little while inflammation is set up and occlusion occurs. Thus, Dr. W. R. White[1] has reported the case of a little girl one year of age, with an obstruction of the intestine caused by woollen carpet-threads which she had swallowed. Dr. N. S. Bates, of the United States Navy,[2] gives a very interesting account of several cases of obstruction in children due to banana-seed. The children were living in Japan, where this fruit formed a large part of their diet.

---

[1] Jacksonian Prize Essay on Intestinal Obstruction, London, 1884.

Dr. H. G. Taylor[3] mentions three cases of intestinal obstruction in idiots, in whom death was due to masses of potato-parings, slate-pencils, sticks, wool fibre, and scybala.

Obstruction may also be caused by masses of intestinal worms, as is shown by a case mentioned in the *British Medical Journal*, 1888, ii. 86, as being reported by Stepp in the *Centralblatt für die medicinisch. Wissenschaft.*, No. 27, 1888. A boy four years old had an acute intestinal obstruction, and died within an hour and a half after medical aid had been summoned. The post-mortem showed the intestines completely occluded by a twisted mass of some forty or fifty round worms, which had lodged just above the ileo-cæcal valve. The ileum higher up contained some thirty-five more, and a few were found in the stomach and œsophagus. He had been given by his mother some "worm medicine" two days before he died, and then the next evening a heavy meal of smoked bacon and sauer-kraut. Dr. Stepp thinks the worms were weakened by the medicine, and were then dislodged in great numbers by the violent peristalsis induced by the injudicious meal the following evening, and so rolled down in a tangled mass too large to pass the ileo-cæcal valve.

Leichtenstern[4] expresses his doubts about the possibility of intestinal worms ever being a cause of obstruction, and considers it not proved; but the case above cited seems to establish the fact.

If the foreign substance swallowed be small and round, it generally passes along the gut, is expelled per anum, and rarely gives any serious trouble. If, however, it be very small, it may drop into the vermiform appendix or some other diverticulum and cause serious mischief.

[3] Lancet, 1887, ii. 255.

[4] Ziemssen's Cyclopædia of Medicine, vol. vii. p. 583.

Sharp bodies, such as needles, may penetrate the walls of the stomach and gradually work their way into some more distant organ.

The symptoms of obstruction by foreign bodies are sometimes very vague and ill defined, and we must depend in great measure upon the history of the case. The diagnosis, consequently, may be difficult. These substances occasionally remain in the stomach for a long time without causing any dangerous symptoms, and are finally vomited, or they pass downward into the intestines. Here they move forward and downward little by little until they reach the ileo-cæcal valve, and if they be not too large to pass this, the narrowest part of the gut, they continue on into the colon and rectum, whence they are either expelled spontaneously or removed by the finger of the surgeon. Sometimes the foreign body can be felt by the hands through the abdominal wall, and its progress followed step by step along the intestinal canal. When, however, it becomes lodged,—and this is most frequent just above the ileo-cæcal valve,—the bowel quickly becomes inflamed, the obstruction by the swelling of the mucous membrane becomes absolute, and a dangerous peritonitis ensues. As the foreign substance moves slowly onward, the little patient has a feeling of great discomfort in the abdomen, with colicky pains, straining, and frequent desire to go to stool, especially when the offending mass is low down. When lodgement in the gut occurs, the pain increases, abdominal distention becomes marked, and a violent peritonitis begins.

Treatment.—It has long been a popular notion that as soon as a child has swallowed a pin, needle, or, in fact, almost any foreign substance, a purgative must be given, in the hope of causing an immediate expulsion of the offending body. For this purpose the mother generally doses the child with castor oil. Nothing could be more injudicious than this plan of treatment, for peristalsis is thereby increased and the foreign body with its sharp points is much more liable to do injury to the intestinal wall. The child must be given food which will have much solid residuum,—oatmeal, unbolted flour, corn-meal, meats, etc.; for experience has shown that by so doing the foreign body becomes surrounded by hardened fæces, which protect the delicate mucous membrane from injury.

Marked success has recently followed the so-called "potato cure" for foreign bodies. Large quantities of potato being eaten, it is claimed that by this the whole intestinal canal is proportionately dilated and the foreign body is prevented from lodging at any point.

When the foreign body becomes lodged in the intestine at a point too high to be reached by the finger in the rectum, laparotomy offers the only chance for life.

A full description of the steps of the operation will be given later on. Here it is only necessary to say that, when the offending body is found, that portion of the gut surrounding it must be drawn out of the belly, the wound packed carefully with sponges to protect the peritoneal cavity from contamination, an incision made into the gut parallel with its long axis, and the foreign substance removed. The wound in the gut must then be carefully cleaned with hot boiled water, and the incision quickly closed by a continuous silk thread introduced with a small cambric needle after the manner of the Lembert suture. A right-angle continuous Lembert suture, as described by Dr. H. W. Cushing ("Boston City Hospital Report," 1889), is quite as effectual as the interrupted one, and much more rapid in its application: the amount of time necessary to make each separate knot of the ordinary Lembert suture is considerable, and there is difficulty in holding the moist and slippery gut.

If the obstruction has persisted for a sufficient length of time for gangrenous changes to take place, an artificial anus, to relieve the acute symptoms, must be formed; or, if the condition of the child warrants a continuation of the operation, resection of the gut and lateral anastomosis by Senn's plates[1] or Abbe's rings[2] or by the ingenious method with small rubber tubing made into a ring by a catgut thread passed through its lumen, as proposed by Brokaw, of St. Louis, in the *Weekly Medical Review* for August 17, 1889, may be undertaken.

VOLVULUS.

Among children volvulus, or the twisting of a portion of the gut upon its mesenteric axis, is rare. It is due to a congenital abnormally elongated and relaxed mesentery.

Leichtenstern[3] mentions the case of a boy aged eleven years who died of pseudo-leukæmia without having any symptoms especially referable to the intestines. At the post-mortem examination a true volvulus of the sigmoid flexure of the colon was found. Mr. Cleland Lammiman[4] reports the case of a child three years old upon whom he performed an unsuccessful laparotomy for acute intestinal obstruction due to volvulus of the sigmoid flexure. Volvulus may also occur in the small intestine and in other parts of the colon, but the most common site is at the sigmoid flexure. The mesentery must necessarily be elongated and relaxed to permit of the gut's rotating upon itself, and in children this elongation is always congenital. Some limited portion of the bowel becomes paralyzed, generally from overdistention caused by the gases evolved in imperfect digestion, and, from the loss of muscular tone, is easily twisted. The loop of intestine within the constriction is always enormously distended; the circulation is at first impeded and finally cut off altogether.

In adults, on the contrary, it is usually acquired, and arises in chronic constipation, from the weight of large masses of fæces, which pull down and drag upon the mesentery, thus causing its relaxation and elongation. It may also arise from long-standing hernial protrusion. Seldom has the congenital condition much to do with its formation.

---

[1] Annals of Surgery, Jan., 1888.

[2] New York Med. Jour., March 23, 1889.

[3] Ziemssen's Cyclopædia of Medicine, vol. vii. p. 562.

[4] Lancet, 1887, ii. 829.

Symptoms.—For some time before the acute attack, it may be days or even weeks, there are evidences of imperfect digestion, flatulent distention of the abdomen, with constipation accompanied by colicky pains. When the twisting of the gut occurs, the onset is sudden, with violent pain, which is not, however, so severe as in strangulation by bands, and is intermittent in character. There is absolute constipation, and no escape of either flatus, mucus, or fæces by the rectum. The abdomen becomes greatly distended with gas, and is soon very tender. Prostration and collapse are not developed so early as in strangulation by bands, neither are they so extreme. Vomiting comes on rather late, and is never very urgent. At first it consists of undigested food, and may finally become fæcal, although the latter condition occurs in only a very small number of cases.

The diagnosis is to be made from the other forms of acute obstruction by the sudden onset, tenderness of the abdomen, meteorism, and absolute constipation. There is no discharge of bloody mucus from the anus, neither can any tumor be demonstrated through the belly-walls or by the finger in the rectum; there are also the character of the vomiting and its late appearance.

Treatment.—Of course the treatment is most unsatisfactory, and, if the volvulus is left unrelieved, death is absolutely certain. Experience has shown that the volvulus can only occasionally be untwisted, after laparotomy has been done, and that almost immediately it will recur. It is possible that puncture or incision of the distended loop of gut, to permit the escape of the accumulated gases, will allow the volvulus to untwist itself, but it has generally been thought better to make an opening into the gut above the seat of constriction, and form an artificial anus.

I would suggest as an improvement that either the untwisted volvulus be sewed fast to the belly-wall at two or three points, so as to prevent its re-twisting, or, perhaps even better, that lateral anastomosis of the intestine be done above and below the volvulus, by Senn's bone plates, Abbe's catgut rings, or other similar means, with resection of the twisted portion of the gut if its life is endangered. Both of these suggestions seem worthy of consideration and trial in so desperate a disorder.

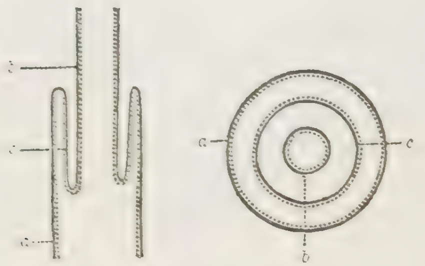
INTUSSUSCEPTION.

A portion of intestine may pass into another adjoining portion, the lumen of the bowel is closed by the resulting pressure, and we have the most frequent form of intestinal obstruction,—namely, invagination or intussusception.

The direction of an invagination is always downward, in the direction of the normal peristalsis; that is, that portion of the intestine which receives the other is always on the lower or anal side. There may be two invaginations occurring at the same time in different portions of the gut, or there may be a second portion of gut forced into an already existing invagination. These are, however, extremely rare.

The intussusception consists of three parts, or layers: a *receiving* or *outside portion*, called the INTUSSUSCIPIENS or sheath, a *middle* or *returning portion*, and an *internal* or *entering portion;* these latter two taken together form the INTUSSUSCEPTUM. The middle or returning portion is literally turned inside out, like the finger of a glove when it is stripped off the hand. All intussusceptions are complete, in that they consist of all the coats of the bowel and enter the sheath evenly.

A glance at the accompanying cut, taken from Mr. Fred. Treves's Essay, the most exhaustive and careful of recent works on the subject, will show the condition very plainly. It will be seen that mucous membrane lies in contact with mucous membrane, and peritoneum with peritoneum, and it can readily be understood how great are the dangers from the cutting off of the blood-supply by pressure and from the rapid adhesions of the two adjacent layers of peritoneum. Treves estimates that three-eighths of all cases of intestinal obstruction are due to intussusception, and that fully fifty per cent. of these occur under the age of ten years, and twenty-five per cent. in the first twelve months of life.



VERTICAL AND TRANSVERSE SECTIONS OF AN INTUSSUSCEPTION.—(*a*) The sheath or intussuscipiens; (*b*) the entering or inner layer; (*c*) the returning or middle layer. (Treves.)

Boys suffer more frequently than girls. Jacobi reports the proportion in his eight cases as six boys to two girls, and Mr. Gay (quoted by Treves) as one hundred and sixty-three boys to ninety-three girls, all under one year of age. This relative disproportion gradually diminishes as the age increases.

Causes.—Many theories have been advanced to account for this condition, and but few have stood the test of time. The one most probable, from all the evidence and from experimentation upon the lower animals, is irregular action in the muscular walls of the intestine. The intussusception occurs at some point in the intestine where there is a limited and severe muscular contraction, and especially is this so with irregular contraction in the longitudinal layer, or where some portion is paralyzed and joined to that which is still active. Hence the division into spasmodic and paralytic invagination; but for clinical purposes this division is of little value. The previous history is of slight importance, for in about one-half of all the cases the children have been reported as perfectly well and strong, when suddenly and without a moment's warning an invagination formed.

Intussusception is most common in infancy, and is frequently associated with the disorders of digestion consequent upon the change of diet from the mother's breast to the milk of cows, and at a time, too, when the nervous processes are most active and peristalsis most vigorous. Diarrhœa (although this is denied by Jacobi), colic, tenesmus, and constipation, all play a considerable part as etiological factors. In one of Jacobi's cases a perfectly healthy child was being jumped up and down in its nurse's arms, when it suddenly cried out with pain: an invagination had formed. Whooping-cough, with its violent paroxysms, is also mentioned as a cause.

Frequently at post-mortem examinations, when death has occurred from some other cause, and where there have been no symptoms especially referable to the intestinal canal, invaginations are found. These are due to a continuation of peristalsis after death, the intestine dying last. They are generally found in the small intestine, show no evidences of inflammatory action, and are reduced with the greatest facility.

A polypoid tumor attached to the wall of the intestine, generally in the neighborhood of the ileo-cæcal valve, or in the transverse colon, may by its presence, especially if there be diarrhœa, increase the muscular efforts of the intestine to such an extent that, by dragging at the point of attachment, an invagination is produced. Mr. Arbuthnot Lane reports[1] the case of a child eight years old who, after an attack of diarrhœa following chronic hip-joint disease, had an invagination produced by such a tumor. It was sessile, and about the size of a walnut. It projected from the anus, and was mistaken by the child's nurse for a prolapse of the bowel, and was returned into the rectum, where it was held by a pad and binder. When its true nature was discovered, the tumor was removed without difficulty, and the invagination reduced.

Invagination may occur at almost any portion of the intestinal canal. Small intestine may slip into small intestine, large intestine into large intestine; but by far the most common position, especially in children, is at the ileo-cæcal valve, which slips into the large intestine. Treves states that the latter condition is found in seventy per cent. of all cases of babies suffering from intussusception. The anatomical relations are such that the slightest alteration in the physiological conditions permits the ileo-cæcal valve to slip into the large intestine, and when once this occurs the peristaltic movements are excited to increased activity by its presence, and the invagination is pushed farther and farther until the rectum is reached, where it may even protrude from the anus. Rarely retrograde, double, and triple intussusceptions are found.

Morbid Anatomy.—When the abdomen is opened after death from acute intussusception, very little is seen at first. Death usually occurs in so short a time after the onset of the condition that the peritoneum is only slightly altered, but the small intestine appears more or less distended and displaced, with its mesentery twisted. The cæcum and more or less of the colon are absent from the normal position, and the colon appears to take its origin from a knob-like mass of the bowel in the course of the ascending or transverse colon. On examining this mass carefully, it is found to be hard, doughy, inelastic, and varying in size from that of an egg to a mass six inches long. It is livid in color, and ecchymotic, showing evidences of great congestion. The condition of the bowel varies very much with the length of time which has elapsed since the invagination formed.

---

[1] Lancet, 1887, i. 731.

If death has occurred within twenty-four hours, as frequently happens from shock, very little else will be seen. When, however, two or three days have elapsed, a mass of inflammatory lymph has been thrown out from the congested peritoneal surfaces, which glues together the invagination and makes reduction, without tearing the walls of the bowel, impossible. Generally the tumor is curved, owing to the twisting and drawing in of the mesentery with the entering layer of the gut, and is of a deep claret-color from extravasated blood. When the constriction has lasted long enough and been of such intensity as to cut off the blood-supply completely, the mucous membrane sloughs, and will be found ash-colored or even gangrenous throughout.

Our attempts at reduction of the invagination by manipulation are generally only partially successful, for, of course, it is only in the most severe cases that we have the opportunity of trying to do this, and great force is required to accomplish the result. The curving of the tumor, with its mesenteric attachments, makes it almost impossible to do it by direct traction without rupturing the bowel, and this frequently occurs when only very gentle force is exercised. Reduction can often be accomplished, provided the adhesive lymph be not too old and firm, by the conjoined use of manipulation of the tumor, as described later, aided occasionally by a forced current of water introduced well up the rectum.

In an ordinary acute case the veins alone are compressed, the arteries still supplying blood, and the gut soon becomes enormously thickened. It is from the venous congestion that the blood-stained mucus comes, one of the most important symptoms in our diagnosis. When the case has been ultra-acute both the veins and the arteries are compressed, the blood-supply is totally cut off, and within a few hours the gut has sloughed. This condition occurs generally in the invaginations of the small intestine, where the pressure will be very severe from the small size of the intussuscipiens.

Symptoms.—The symptoms in an acute case (and this is most frequent in children) are very sudden in their onset when the invagination is at the ileo-cæcal valve, and rather more gradual when it is situated in the colon and rectum. The child is apparently perfectly well, when suddenly, while exercising, or, it may be, during sleep, it is seized with acute colicky pains and cries out violently; the pains are paroxysmal in character, due to the irregular peristalsis, and rapidly increase in severity.

The abdomen at first is soft, and not at all tender to the touch, and it may even give the little patient comfort to apply gentle pressure with the hand. This condition of affairs soon changes as congestion and peritonitis set in, and the abdomen becomes distended, tympanitic, and painful. Signs of collapse very soon appear; the face grows pallid and anxious, the eyes become sunken, the skin is covered with a cold sweat, and the pulse is rapid and weak.

Vomiting sets in, but not so early nor so constantly as in strangulation of the gut in hernia or by bands. At first the vomited matter is undigested food, and it becomes fæcal in only about twenty-five per cent. of the cases. Sometimes when the invagination is in the small intestine blood is vomited. This is due to the intense congestion at the point of invagination, and is very rare in the ileo-cæcal variety. One case, at least, has been reported in which vomiting was excited by the introduction of the finger into the rectum for purposes of diagnosis: at each repetition the vomiting recurred. In the chronic variety vomiting may be absent altogether, or not at all constant. Mr. R. W. Parker[1] reports two fatal cases of intussusception in infants three and four months of age respectively, in which vomiting occurred only during the first twelve hours, and then only after taking the breast. He explains this by the fact that the invagination was very acute and the gut speedily became gangrenous.

When the invagination exists in the small intestine, indican will be found in the urine.

Generally there is diarrhœa at first, an unloading of the intestine, especially below the constriction, with violent peristalsis and tenesmus. After the first few hours, or in very acute cases almost immediately, the discharge becomes the characteristic blood-stained mucus. Mr. Treves mentions one case of ultra-acute invagination in which the discharge of blood by the bowel was so great as to cause death from the hemorrhage. Tenesmus is rarely absent, and increases in severity the nearer the intussusception is to the rectum; although Mr. Parker states that in the cases of fatal invagination just mentioned there was no straining or tenesmus whatever. Generally, after the first few hours, constipation is marked.

The temperature at first is normal or nearly so, but as the urgency of the symptoms increases, and the shock grows more profound, it becomes subnormal. Thirst is a constant and distressing symptom, but depends in a great degree upon the vomiting and sweating, increasing with their severity. The flow of urine is slightly diminished, and this is most marked if there is profuse sweating. The higher up the seat of the obstruction, the more marked is the diminution in the quantity of urine.

In a large proportion of the cases a tumor can be demonstrated by *careful* palpation of the abdomen, and is of the utmost importance in diagnosis. A sausage-shaped, doughy, inelastic mass may be detected in some portion of the colon, generally on the left side in the descending colon; it is curved, owing to the tension of the mesenteric attachments. At the very onset this tumor will exist most frequently just above the cæcum, but as more and more of the bowel becomes invaginated the tumor gradually changes its place, following the course of the colon, till it is finally found on the left side. It varies in size from that of an egg upward, but is rarely longer than six inches. A careful examination of this mass during a paroxysm of pain is important, to determine if its size or tenderness is increased, as well as to learn whether it is fixed or movable.

---

[1] British Medical Journal, June 2, 1888.

Frequently the intussusception can be felt by the finger introduced into the rectum,—a mass smooth and rounded, not unlike the cervix uteri, though softer, with a rounded slit-like opening in its centre, the lumen of the gut. This may even protrude from the anus, and in at least one instance it has been excised in mistake for a polypoid growth.

Chronic cases of intussusception in children are almost always of the ileo-cæcal variety, and may last for several months, causing only ill-defined symptoms. Strangulation, as a rule, does not occur, and the mass of ensheathing lymph which so tightly binds together an acute invagination does not form. This condition of things may remain for weeks or even months, the little patient suffering more or less pain, with partial obstruction to the passage of fæces, while the invagination is gradually being forced downward by the peristaltic movements, and frequently, as has been said, protrudes from the anus. The pain at first is paroxysmal, and there may be long intervals during which it is entirely absent. After a time there may be vomiting, but this is not constant.

The lumen of the bowel is not entirely closed, and fæcal matter from above the seat of invagination is permitted to pass. The condition grows gradually worse: the discharges from the bowel become mucoid, and finally bloody,—an especial characteristic of intussusception,—the pain increases in severity and is more persistent, the vomiting becomes constant, and the little sufferer finally dies of exhaustion.

At any time these chronic cases may suddenly take on acute symptoms. A tumor, if carefully searched for, will be found, with its characteristic doughy feel and sausage-shaped outline, in the ascending, transverse, or descending colon, and the finger in the rectum will be able to detect the advancing invagination. A point in the diagnosis between chronic invagination and fæcal impaction is the fact that the tumor in invagination moves its position and gradually advances, while the tumor of fæcal impaction remains stationary.

Diagnosis.—The diagnosis may be very easy, or most difficult. When a child seemingly in perfect health is taken with sudden and intense pain, followed by vomiting, and by the passage of blood-stained mucus from the anus accompanied with violent straining; when, after the unloading of the bowel below the constriction of what fæces it contained, there is constipation, and after a time collapse; and when a tumor is found in the abdomen which follows the line of the colon, and which changes its position and can possibly be felt by the finger introduced into the rectum,—all doubt must at once be at an end. If the character of the tumor which is felt through the abdominal walls is doubtful, and nothing can be found by the finger in the rectum; if it does not contract or change its position under the hand,—then, to solve the question, an injection of water should be used. If, however, the above-mentioned signs are present, little if anything can be gained and everything may be lost by delay in taking active measures for relief.

The constriction of the invagination by the ensheathing layer causes inflammation and sooner or later a sloughing off of the invaginated portion of the bowel. Sometimes the sloughing process does not take place for a long time, and we may never expect it in children under two years of age; for with them the inflammation of the bowel is almost certain to terminate fatally within from thirty-six hours to three or four days. We may sometimes, however, expect this termination in children of six years and upward, though even with them it is not the common result. Even after the invaginated portion has sloughed and come away, the child is still in danger from ulceration and possibly constriction of the gut by cicatricial bands or contraction. It seldom entirely recovers, but dies, it may be months afterwards, of exhaustion.

Mr. Harrison Cripps[1] reports the case of a child seven months old who when brought to him had been ill for a fortnight, with an intussusception which hung outside the anus and was in a gangrenous state. The slough came away bit by bit each day for a month, when the child was discharged from the hospital cured. Subsequently the child died of scarlet fever, and at the autopsy the small intestine was found attached to the anus. There were no traces of the ascending, transverse, or descending colon: these must have all sloughed away.

Dr. Obtulowicz reports[2] the case of a boy thirteen years old who after a fall had violent pain in the right iliac region, which was shortly followed by bloody mucous stools. He had pain and a bloody diarrhœa for two weeks, when a tumor was noticed in the region of the pain. A week later he passed at stool a piece of dead bowel twenty centimetres long, which consisted of the cæcum, with its appendix vermiformis, and an invaginated portion of the ileum, together with a fragment of the mesentery. The boy made a good recovery, but was again injured, and died after a year's illness, it was supposed from fæcal extravasation.

All intestinal obstructions in young children have a tendency to run an acute course, and, unless active measures for relief be instituted within a few hours after the onset of the disease, death quickly ensues. In chronic obstructions, on the contrary, the prognosis is not necessarily so grave, as spontaneous recoveries have been known to occur (*vide supra*); but this happy result must not be expected in the vast majority of cases.

Treatment.—Intussusception in children when unrelieved is so rapidly fatal, and the statistics of large numbers of cases show conclusively that the delay of even a few hours is so unwise, that, as soon as a diagnosis is determined upon, a definite course of action should be instituted, and attempts made by some means to replace the invaginated bowel.

Purgatives must not be given under any consideration whatever, as they can do no good, and will do positive harm by increasing the peristaltic movements of the bowel and so produce further invagination and possibly rupture of the gut. Opium in some form (and opium itself is better than one of its preparations) is absolutely demanded. It diminishes pain and consequently shock, it arrests the excessive peristalsis, thus preventing further invagination, and by its power of allaying irritation it may possibly permit of spontaneous reduction of the intussusception. Great care in its administration must be exercised, lest its soothing effects give false confidence, and other measures of relief must be used in conjunction with it.

---

[1] British Medical Journal, June 2, 1888.

[2] Annals of Surgery, July, 1889, p. 77,—a translation from Wiadomosci Lekarskie, October, 1888.

In the early stages, within two to three days, before firm adhesions have formed, unless the symptoms be ultra-acute, the child should be placed under the influence of an anæsthetic and attempts made to reduce the invagination by means of enemata of warm water. The child, when thoroughly under the influence of the anæsthetic, is placed on a soft pillow, with the hips raised, and, warm water in a fountain syringe being in readiness, the injection-pipe is introduced well into the rectum, and the water allowed to flow by gravity and quite slowly into the bowel. The utmost gentleness must be exercised throughout the manipulations, and no sudden forcible injection used: the force of the column of water is to be regulated by raising or lowering the bag of the syringe. At the same time gentle manipulation of the abdomen is to be made by an assistant. If this be not successful at first, the child should be inverted,—a manipulation of great importance, as gravity will materially aid in the reduction. In an excellent paper in the *American Journal of Obstetrics* (1886, p. 673) Forest gives the result of both clinical and experimental studies on this subject. He has shown that such injections are of little if any use in the small intestine, and that the large bowel bore a pressure in children of eight or nine pounds to the square inch before it ruptured. He therefore advises that the child be taken into the hall (so as to get sufficient height) and that the bag of the fountain syringe be gradually raised until it is fifteen to twenty feet above the child's hips. Each two and a half feet of height will represent one pound to the square inch. The tube of the syringe will have to be correspondingly lengthened. The nozzle recommended is to be large (as the sphincter is dilated), and he has used a glass vaginal syringe resembling a test-tube. It must have a good shoulder of bandage, to occlude the anus. I am decidedly inclined, however, to recommend not to use a pressure above five to six pounds (*i.e.*, twelve to fifteen feet), as I think that Forest has not given sufficient weight to the softened condition of the bowel when invaginated,—a condition that did not exist in the children's cadavera upon which he experimented.

Insufflation by means of bellows may be resorted to in the early stages and in subacute cases, and also hydrogen gas by Senn's method for intestinal wounds.[1] Mr. R. Clement Lucas[2] considers air much safer than water, which latter he thinks gives too much lateral pressure and is too heavy, and is therefore much more liable to cause rupture of the intestinal walls. He makes the point, also, that the large quantity of water thrown into the bowel is likely to produce subsequent diarrhœa. It must be borne in mind that the gut is always in a weakened state, and it may be gangrenous even at an early period, if the constriction is great; much force, therefore, may readily cause rupture of its wall, and escape of its contents into the peritoneal cavity, with certain death as a result. Hence air, like water, must be injected gently and gradually.

---

[1] Jour. Amer. Med. Assoc., June 23, 1888.

[2] Lancet, 1886, i. 96.

Mr. Harrison Cripps (*loc. cit.*) gives an account of the dangers of forcible distention of the gut after it has been weakened by inflammatory action. A child eighteen months old had for four or five days been ill with symptoms of intussusception. Injections of water with a Higginson's syringe were made in an attempt at reduction of the invagination, and considerable force in the stream of water from the syringe was used. Suddenly the child was seen to become faint, collapsed, and died in three or four minutes. The post-mortem examination showed that the intussusception was firmly held together by the inflammatory exudate, and a rent several inches long had been made in the gut by the forcible current of water.

Many methods have been used, and still more suggested, to reduce the invagination, some of which may only be mentioned to be condemned.

Oil has been used as an injection, and may be of service.

Carbonic acid gas, made by introducing the alkali and the acid of a Seidlitz powder separately and allowing the evolution of the gas to take place in the bowel, has been suggested. This should be condemned for the danger which such an uncertain force could give rise to. A siphon of soda or seltzer has been used by Forest and others with good effect.[1]

Metallic mercury, allowed to run by gravity through a rectal tube, has been used, and it has also been given by the mouth, in the hope of overcoming the obstruction. The good which has been claimed for this method of treatment is due to the fact that the mercury when given by the mouth becomes divided into very fine globules, which might work their way through the obstruction, rather than to the weight of the mercury itself.

Success in the reduction of acute invaginations by the injection of water or of air can be expected only within the first forty-eight hours, for, although it has been successful later in the disease, the dangers of rupture of the intestine increase in exact proportion to the number of hours which have elapsed since the invagination occurred.

If these measures are of no avail, we must recollect that the invaginated bowel is every hour becoming more difficult to deal with and the danger rapidly increasing. The circulation is becoming more and more impeded, the congestion greater, and the peritonitis more intense. Lymph is being thrown out rapidly, which will glue together the coats of the bowel involved in the invagination and soon make reduction by direct manipulation impossible. To quote Mr. R. Clement Lucas again,[1] "To hesitate, dally, postpone, is to trifle with nature;" and we must proceed at once to open the abdominal cavity, search for the invagination, and, if possible, by manual efforts accomplish its reduction.

---

[1] Loc. cit.

In chronic invaginations injections of water, and inflation with air by the bellows, have a good chance of success. Purgatives do great harm, as they only tend to hasten peristalsis and strangulation, with its grave consequences. In this (the chronic) form of invagination we have the greatest chance of success from laparotomy, as strangulation has not occurred, and the gut is not softened nor firmly bound by the lymph which in acute cases is always present.

The question of laparotomy in children for acute intussusception is one upon which much has been written, both *pro* and *con.* The published statistics are far from encouraging, for children bear very badly the shock of opening the abdominal cavity. But when we consider the absolutely hopeless condition if the remedial measures already suggested have been tried and have failed, and the cases recorded of complete recovery even in children as young as six months of age,[2] we ought not to hesitate, but should at once proceed with the operation.

Laparotomy.—The room in which the operation is to be performed must be warm—at least 75° F., and better 80° F.—and well lighted. Eight or ten bottles filled with hot water should be laid around the little patient, so as to prevent shock as much as possible.

If there be much abdominal distention, with rapid respiration, due, in part at least, to pressure against the diaphragm by the distended coils of intestine, it is best to wash out the stomach with warm water before giving an anæsthetic. This can be accomplished, if the child is old enough to do so, by getting it to drink warm water and then vomit, repeating this several times; or a small rubber tube can be passed into the stomach and its cavity thoroughly siphoned out. This will greatly relieve the abdominal distention and respiratory distress, thus diminishing the risk of the anæsthetic. Mr. Greig Smith[3] makes such a point of this that, with adults at least, he much prefers local anæsthesia by cocaine, or no anæsthesia at all, in all cases of meteorism, and thinks the dangers of increased shock much less than the dangers consequent upon the administration of the anæsthetic itself with the gaseous distention unrelieved. Chloroform carefully administered and well mixed with air is to be preferred.

The instruments necessary are those required for an ordinary laparotomy: a scalpel, half a dozen hæmostatic forceps, a grooved director, scissors, catgut and fine silk for ligatures and sutures, Hagedorn needles and a needle-holder, some fine cambric needles and fine sewing-silk for suturing the gut if it should be opened or have to be otherwise operated upon, with one or two sponge-holders or long hæmostatic forceps to be used as such. They must all have been boiled for at least ten minutes, and then placed in a five-per-cent. solution of carbolic acid. All instruments, needles, and sponges must be counted before the operation, and again immediately before the abdominal wound is closed. Just before the operator begins his incision they should be taken out of the solution and placed in hot, boiled, filtered water. In this way they are rendered thoroughly aseptic, and yet there will be no danger of irritating the skin of the hands or of introducing any of the carbolic acid into the abdominal cavity, which is not well borne by children. It is well to have in readiness, also, some of Prof. Senn's bone plates, or, what are more convenient, Dr. Robert Abbe's catgut rings of small size, or Brokaw's rubber rings, to be used if necessity arise for resection of the gut.

---

[1] Lancet, 1886, i. 98.

[2] Abdominal Surgery, p. 424.

[3] Sands, New York Medical Times, June, 1877.

Several ordinary surgical sponges and two or three moderately large flat ones must be in readiness, as well as plenty of hot water which has been boiled and filtered. A fountain syringe with glass nozzle, for flushing the abdominal cavity, is also needed ; or, if this be not at hand, a small pitcher with a rather sharply pointed lip will answer the purpose very well.

Plenty of corrosive-sublimate gauze will be required, not only for the purpose of dressing the wound, but also, if the operation be done suddenly, to be used in place of the towels wrung out of corrosive-sublimate solution so generally used at laparotomies to surround the field of operation. These wet towels materially increase the dangers of the operation, for young children cannot withstand the shock of the disease and the additional shock of the operation unless they are both dry and warm. The child must therefore be wrapped in warm dry blankets, and be surrounded by the hot-water bottles already mentioned, and there should be as little exposure of bare skin as possible. If time allows of such preparation, the field of operation may be covered, as for some years has been my own custom in all operations, by towels which have been wrung out of a one to one-thousand corrosive-sublimate solution a few hours before the operation and rough-dried in a clean room.

When the child is thoroughly under the influence of the chloroform, it is placed on a table in a good light, with its head not too high ; with little children no pillow whatever should be used. Next the skin of the abdomen must be thoroughly scrubbed with soap-and-water with a nail-brush, then with ether to remove all grease, and finally with a one to four-thousand solution of corrosive sublimate. This for very young children is quite strong enough as a germicide : stronger would be likely to blister the skin.

The hands and forearms of the operator and assistants—of whom he ought to have three, one to give the chloroform, one to assist him with the wound, and one to attend to the sponges—must have been rendered thoroughly aseptic with nail-brush, soap, water, alcohol, and a one to one-thousand solution of corrosive sublimate.

The urine must be drawn by catheter if it has not been passed immediately before. An incision sufficiently long to admit two fingers should be made in the linea alba midway between the umbilicus and the pubes, for this gives the best command over the whole abdominal cavity. The tissues should be rapidly dissected down to the peritoneum, and all bleeding points secured. The peritoneum should then be caught up between two pairs of forceps and opened.

The greatest care must be exercised to prevent the escape from the abdominal cavity of the distended bowel, which now pushes itself into the incision, for experience has shown (and this is especially the case in children) that the dangers in laparotomy are increased in proportion to the amount of gut permitted outside the belly-walls. If, however, the gut is very much over-distended, thereby interfering with proper manipulation, a portion of it may be drawn outside the belly, and, after packing carefully around it flat sponges, so as to shut off completely all communication with the peritoneal cavity, an incision with a knife is made longitudinally, and the intestinal contents are allowed to escape. If this be done with a sharp knife, thus making a clear-cut wound, the distention can be relieved, and the wound rapidly closed with fine silk and a cambric needle by a continuous right-angle Lembert suture, without materially increasing the danger to the patient. A clean incision is much to be preferred to the introduction of a trocar and canula, as is so frequently advised, for the latter makes a ragged contused wound, very difficult to close securely. Puncturing the gut with a fine needle is also most unsatisfactory, as it does not permit of complete emptying of the contents and might allow of fæcal extravasation. The greater the speed with which the operation can be performed (no undue haste, of course, being permitted), the better are the chances for ultimate success, as the shock is thereby greatly lessened.

As soon as the fingers are in the abdomen, search should be made for the cæcum, and, using this comparatively fixed point as a guide, the exploration should continue, inch by inch, in the direction of increased distention and congestion of the gut, until the intussusception is found. Often this is a matter of great difficulty, and it may be necessary to enlarge the incision before it can be accomplished.

When the tumor is found, attempts should be made at reduction with the parts *in situ,* as was successfully done by Dr. Snowball in a case reported by Mr. Workman;[1] but usually it will be necessary to draw the tumor outside the belly and pack around it flat sponges wrung out of hot boiled water, thus preventing further escape of gut and protecting the peritoneal cavity. If the condition of the gut is good and the amount of inflammatory lymph not too great, it should be taken in the fingers of the two hands, and, while with one hand gentle traction is made upon the entering portion, efforts should be made at the distal or ensheathing portion with the other hand to push the invagination backward and out. This is best accomplished by the same sort of movement as one would use in taking a ripe cherry between the fingers and pinching the stone out. In a recent case in which I operated, direct traction alone failed, but the combined manipulation above described released the invaginated portion in a few moments.

---

[1] Lancet, 1888, ii. 888.

The mesentery is drawn in with the invaginated gut, and by its traction the tumor is curved to almost a semicircle, which makes it impossible by direct traction to withdraw the entering portion of the invagination.

The special point to be borne in mind in all ileo-cæcal invaginations—and it is with this variety that we have, of course, the most to do—is that our efforts at reduction must be persisted in, using gentle force, until the vermiform appendix appears, for until this is freely seen the reduction is not complete, but will immediately recur.

When the invagination is so firmly bound with inflammatory lymph that our efforts at reduction are unavailing, or when the inflammation has been so intense or the interval since the onset of the attack so long as to be followed by gangrene, an artificial anus should be made. To do this we must draw out the gut from the abdominal cavity until we find healthy tissue both above and below, the peritoneal cavity being carefully protected by hot sponges. The sound gut is then stitched with silk sutures to the external skin in an angle of the abdominal wound, and the gangrenous portion excised. The peritoneal cavity must then be thoroughly washed out with hot boiled water, and the angles of the wound closed.

An attempt at resection of the gut at this time in children is usually far from wise, as the shock of the operation added to the shock of the pathological condition is too great for them to withstand. We should, therefore, leave for a subsequent operation the re-establishment of the continuity of the intestinal canal.

INTERNAL STRANGULATION OR OBSTRUCTION OF THE BOWELS DUE TO CONSTRICTION.

Strangulation by *bands* (fibrous bands due to a previous peritonitis) are occasionally met with. They are generally due to intra-uterine peritonitis, for an inflammation of the peritoneum in young children is usually so violent that death quickly ensues,—too quickly for such bands to form. There is, however, a form of strangulation due to stricture of the gut following strangulated hernia. When a strangulated hernia has been inflamed and the bowels are glued together by an outpouring of lymph, this lymph, which is soft, may stretch by the continual pulling of the peristaltic action of the intestines, and become a fibrous band.

There are two methods by which strangulation by these bands may occur: either a knuckle of gut may pass under and be held down by the band, or a piece of gut may become twisted around the band; in both instances a violent muscular effort or strain might produce this. Adhesions binding down the vermiform appendix, following an attack of perityphlitis, will cause a strangulation of the gut in the same way.

Sometimes, as the result of traumatic forces, a slit is torn in the mesentery, or through the diaphragm, of sufficient size to permit a knuckle of gut being forced in and constricted. This is an extremely rare condition, and especially so before the age of ten years.

In *Meckel's diverticulum* we have also another cause of strangulation. This diverticulum is an incomplete closure of the vitelline duct, and may extend as a tube, sometimes simply as a cord, from the umbilicus to the lower portion of the ileum. It is similar in structure to the small intestine. It generally comes off from the bowel as a blind tube, and the abdominal end opens into the lumen of the bowel. It has remained open as late as twenty years after birth, as a channel through which fæces pass to be discharged at the umbilicus. When a knuckle of gut is caught beneath this membranous cord, the circulation is completely cut off, and an acute strangulation results.

Mr. Pye-Smith[1] reports the case of a boy thirteen years old who had suffered from an acute intestinal obstruction for four days. He performed laparotomy, and the constricting band was Meckel's diverticulum attached at its extremity to the mesentery. The arrangement was peculiar. The diverticulum was a little over two inches in length. It came off from the bowel at almost a right angle between the mesenteric and free borders; it then passed through an opening in the mesentery of the part of the bowel from which it sprang, and closely encircled the bowel, immediately above its origin; its extremity was firmly attached to the mesentery, half an inch or more above the opening through which the diverticulum passed. Thus the constriction was not of a coil or knuckle of intestine, but of the tube at one level only, as if a cord had been tied around it at that spot. The bowels were moved spontaneously in twelve hours after the constriction was relieved, and a bit of fish-fin three-fourths of an inch long by one-fourth of an inch wide was passed. This had lodged above the constriction and precipitated the acute symptoms.

In tuberculosis the *mesenteric glands* may ulcerate and set up an inflammation by which the gut may become constricted. Likewise an acute localized *enteritis* may cause a narrowing of the lumen of the gut and consequent obstruction. Mr. Percy Potter[2] reports a case of this unusual form of obstruction affecting the ileo-cæcal valve which came under his care at the Kensington Infirmary.

A girl five years old was admitted with intestinal obstruction of a week's duration. The countenance was pinched, the pulse small and weak, the abdomen flattened and especially tender over the right iliac region; the child lay on the left side, with the thighs flexed. She was restless; her tongue was brown and dry; the temperature was not increased; vomiting had been frequent, and was then persistent, but not fæcal.

Palliative measures failed, and laparotomy was done. The intestines were exposed and traced from the duodenum downward; this and the first part of the jejunum were distended with flatus, whilst chyme was felt to be present in the lower part of the small intestine. The large bowel was empty. There were no signs of peritonitis, old or recent; the abdominal contents, so far as could be seen, were healthy. Objective signs of obstruction were absent. The child died from collapse six hours after the operation.

---

[1] Lancet, 1889, i. 472.

[2] British Medical Journal, 1888, ii. 1045.

The post-mortem examination, made seventeen hours after death, showed no signs of commencing peritonitis, and all the organs of the chest and abdomen were apparently normal. The intestines were removed and filled with water, and it was found that the ileocæcal valve was impervious; no fluid entered the lower bowel. The last few inches of the ileum were found to be the seat of enteritis; flakes of inflammatory lymph had agglutinated the edges of the valve to such an extent that only a pin-hole remained, through which water could percolate drop by drop. No foreign body existed in the vermiform appendix, nor was anything found in the intestines to cause inflammation. The obstruction was centred solely in the interior of the bowel.

Prognosis and Treatment.—The prognosis in acute intestinal obstruction due to bands, Meckel's diverticula, and to internal hernia through apertures in the mesentery, unless the condition is relieved by surgical means, is absolutely fatal. Palliative medical measures are worse than useless, as valuable time is thereby lost, the strength of the patient diminished, and inflammatory changes in the constricted gut needlessly increased.

As soon as a diagnosis is made, the belly must be opened, the constricting band searched for, and the gut released. All the precautions and details mentioned in describing laparotomy for intussusception must be observed.

When the constricting band is found, a ligature is to be applied to both ends of the band and the intervening portion cut away.

If the constriction be a Meckel's diverticulum, the distal end must be freed from its attachments, the intestinal end brought outside the belly, the peritoneum being carefully protected by warm aseptic sponges, and the diverticulum cut away. The cut end must then be inverted, and the peritoneal surfaces of the stump so formed brought together by a continuous Lembert suture of fine silk and a cambric needle, completely shutting off the interior of the tube. It is then to be carefully cleansed by a one to four-thousand solution of bichloride of mercury, washed again with boiled water, and returned to the abdominal cavity, which is then to be flushed with warm boiled water, and the external wound closed. If there be any uncertainty as to the absolute closure of the cut ends, it will be better to introduce a drainage-tube and allow it to remain for twenty-four hours. This tube should be of glass, with fenestræ, and passed through a hole in a sheet of disinfected "rubber dam," and the dressing applied around the end of the tube. The sheet of rubber is then to be gathered up, a mass of gauze put in its opening, and pinned securely. This mass of gauze must be examined every two hours, and as soon as it is stained by the discharge it must be renewed. If the temperature rises above 100° F. the abdominal cavity must be flushed out with warm boiled water at intervals of four or five hours.

If the constricting factor is found to be a slit in the mesentery or diaphragm, the gut must be released, a stitch of catgut passed through the sides of the opening, and an attempt made to close it.

No mention has been made in this article of obstruction due to fæcal impaction, as this subject and its treatment are fully considered in another portion of the work, and need no further mention here.

Diagnosis.—The differential diagnosis between the various forms of intestinal obstruction may be exceedingly difficult.

In obstruction by foreign bodies there is often a history of swallowing some substance, or of some great imprudence in diet, which will aid us; and occasionally the outlines of the obstructing mass may be felt by the hands through the abdominal walls, and followed on its downward journey.

With volvulus we have a history of digestive disturbance, sudden pain which is moderate at first and intermittent in character, and rapid and marked meteorism. There is moderate prostration, with tenderness almost at once of the abdomen. Vomiting also is not a distressing symptom.

In intussusception, by far the most common form with which we have to deal, there is the absence of a history of ill health; there is the sudden onset of pain; tenesmus, and vomiting which soon becomes fæcal; the passage of blood-stained mucus from the bowel; a tumor in the abdomen, which is movable, and can frequently be detected by the finger introduced well into the rectum; and great prostration, with early collapse.

With obstruction due to constrictions the diagnosis is very difficult, and to determine the variety is frequently impossible. When the constriction is by bands, there will generally be a history of pelvic inflammation; when by slit or through an aperture, a history of injury. The onset of the attack is very acute; the pain is intense, continuous, and with exacerbations; vomiting begins early, is exceedingly urgent, and soon becomes fæcal; while the prostration and collapse are very profound. There is no abdominal distention until later in the disease.

In order that the differential diagnosis may possibly be made clearer, the tabular statement on the following page is presented. Given a clear diagnosis, the question of surgical treatment becomes easy. It is in the diagnosis that the chief difficulty lies, and here is the greatest room for progress.

DIFFERENTIAL DIAGNOSIS.

FOREIGN BODIES.	VOLVULUS.	INTUSSUSCEPTION.	CONSTRICTIONS.
	Very rare.	Most common.	Next in frequency to intussusception.
History of swallowing foreign substance.	History of constipation and digestive disturbance.	History of no moment.	History of injury, of peritonitis, or at least of pelvic pain.
Onset gradual.	Onset sudden.	Onset very sudden.	Onset very sudden.
Pain is moderate, and increases only with the extending peritonitis.	Pain moderately severe at first, intermittent, and increases in severity.	Pain acute, paroxysmal, wave-like, increasing and diminishing.	Pain very acute, continuous, but with exacerbations.
Prostration not so marked as in other obstructions.	Prostration and collapse not very extreme.	Prostration and collapse extreme.	Prostration and collapse extreme.
Tenderness of abdomen is early and rapidly increases, with tympanites.	Tenderness of abdomen early, and gaseous distention extreme.	Abdomen retracted; no distention; no tenderness at first, gentle pressure grateful.	No tenderness or abdominal distention until very late.
Vomiting is very late in coming on, and is never urgent.	Vomiting late, never urgent, and in a very small number of cases fæcal.	Vomiting from the first frequent and copious, and may be fæcal.	Vomiting from the first very frequent and copious, and soon becomes fæcal.
Constipation becomes absolute.	Constipation absolute, no discharge whatever from anus.	Fæcal discharge if the intussusception be not too acute, an unloading of the bowel below the constriction.	Constipation absolute.
Tenesmus is marked, especially if the obstruction be low down in the bowel.	No tenesmus.	Tenesmus with discharge of blood-stained mucus from anus. (Important.)	No tenesmus.
The foreign substance may sometimes be felt through the belly-wall and followed step by step downward.	No tumor.	Tumor felt through abdominal walls. Tumor contracts beneath the hand during a paroxysm of pain, and changes its position, following the course of the colon.	No tumor.
Foreign substance may sometimes be felt in the rectum.	Nothing by rectum.	Finger in rectum will sometimes feel the end of the invagination.	Nothing by rectum.
Prognosis is less grave than in other obstructions. Surgical measures must be used after medical measures fail.	Death absolutely certain if unrelieved by surgical means.	Prognosis always grave if unrelieved by surgical means. Occasionally adhesions form between the entering and ensheathing layers, and the intussusception sloughs and comes away. This result is rare in children, and must never be expected under two years of age, and only in subacute cases.	Prognosis absolutely fatal unless relieved by laparotomy.

PERITONITIS.

By HENRY ASHBY, M.D., M.R.C.P.

Peritonitis occurs at all ages, and is due to a variety of causes: it occurs during intra-uterine life, in the newly-born, and during infancy and childhood.

During early life peritonitis cannot be said to be a common disease; the peritoneum appears to take on acute inflammation less readily than the serous membranes covering the lungs or the brain; and in comparing the frequency with which it occurs at different ages we must bear in mind that, in the adult, lesions of the ovaries, of the Fallopian tubes, and of the uterus more often give rise to peritonitis than any other cause. Before puberty a peritonitis resulting from these causes does not occur.

INTRA-UTERINE PERITONITIS.

Many years ago the late Dr. Simpson,[1] of Edinburgh, called attention to the fact that in still-born children, or in fœtuses dying in the later months of intra-uterine life, a peritonitis was present which was evidently the cause of death. He further noted the fact that syphilis was frequently present. These observations have been confirmed since, and syphilitic lesions of other serous membranes, as meningitis and pleurisy, have also been found in still-born infants. Evidences of a prenatal peritonitis are not infrequently found after birth, in the form of adhesions and bands which connect the small intestines together, and in some cases constrictions or a narrowing of portions of the intestines have taken place as the result of cicatrization of bands and adhesions. In such cases death may result within a few days or a week of birth, with all the symptoms of intestinal obstruction. Such cases are not uncommon: a typical case is recorded by E. Owen,[2] in a newly-born infant, in which the ileum was constricted by old adhesions a few inches above the ileo-cæcal valve. Another case, in which the jejunum was constricted by old fœtal peritonitis, is recorded by Kirchner.[3]

[3] Berlin. Klin. Wochenschrift, 1886, No. 27.

No symptoms, so far as is known, are present in fœtal peritonitis; and if not fatal before birth, its results—that is, the adhesions which form—are exceedingly likely to lead to an interference with the development or to constriction of a portion of bowel.

PERITONITIS IN THE NEWLY-BORN.

Acute peritonitis in the newly-born is practically always septic, the result of unhealthy inflammation at the navel, or the absorption of septic material at this spot. It is uncommon in private practice, occurring in the large majority of instances in lying-in institutions. The infection is probably conveyed to the infant at the time the cord is tied, either by the fingers of the nurse or by the use of infected dressings. The early symptoms are usually those of a local inflammation, with erysipelatous redness around the attachment of the cord. There may be vomiting, diarrhœa, jaundice, distention of the abdomen, fever, and wasting. It must be remembered that peritonitis is only occasionally present in puerperal septicæmia of the newly-born. Indeed, according to Runge, it is not a common one, for of fifty-five post-mortems in infants dying of arteritis umbilicalis and septicæmia the result of puerperal infection, in only four was there peritonitis, pleuro-pneumonia being much more common. In puerperal peritonitis death mostly occurs within a week. The diagnosis is not difficult if evidence of inflammation about the navel be present. The treatment is almost entirely preventive.

PERITONITIS DURING INFANCY AND CHILDHOOD.

The peritoneum necessarily shares the fortunes of the organs which it surrounds, in this respect resembling other serous membranes, especially the pleura, taking on an acute inflammation in consequence of its close contact. It is also liable to acute inflammations which are primary, the result of some morbid state of the blood, as in Bright's disease or septicæmia, or are the result of injury. It is also liable to an acute—though more often a chronic—inflammation from the presence of tubercle. Acute peritonitis is sometimes "idiopathic," or at least arises without any cause being traced either from contact with or a spreading from some neighboring inflammation: in such cases the inflammatory lesion has been attributed to a "chill" or to the "rheumatic" state of the system.

An acute general peritonitis which is secondary may follow as a consequence from perforation of the cæcal appendix or some inflammation around the cæcum, a perforation of the ileum in enteric fever, or a perforation of the diaphragm in a case of empyema. A general peritonitis will sometimes supervene in empyema without any perforation being present, the lymphatics being apparently the channel through which the inflammation spreads.

A primary or idiopathic general peritonitis without any local cause being discovered is not uncommon: it is needless to say that no case should be referred to this category without a most searching post-mortem examination. Some of these cases are septic, there can be little doubt, though in what way the poison enters the system cannot be said. In some cases there is a history of a blow, perhaps contracted in the football- or cricket-field; in many cases, however, such blows are insufficient to explain the acute inflammation which has followed. In some cases the attack is in reality an entero-peritonitis, an enteritis or an acute intestinal catarrh being the starting-point. Certainly patches of intense congestion of the mucous membrane may be found in acute cases of peritonitis: it is not improbable that some animal poison or microbe may be taken into the alimentary canal and give rise to an enteritis which quickly involves the peritoneum.

An acute inflammation may be sero-fibrinous, or the fluid present may be pus; the inflammation may be general, or a circumscribed patch of lymph or an abscess may be present.

Symptoms.—The early symptoms of peritonitis may be interwoven with or supervene on those of some pre-existing lesion; or they may be modified in consequence of being secondary. There may be some diarrhœa, with pain and tenderness in the ileo-lumbar region, suggestive of a peri-cæcal inflammation; then suddenly collapse and continued vomiting point to a general acute inflammation. The symptoms of peritonitis may be indefinite for a while, the result, perhaps, of a suppurating mesenteric gland or local abscess, to be followed by those of an acute general peritonitis. A child may be suffering from scarlatinal nephritis, pass into more or less of a uræmic condition, then abdominal distention, pain, and tenderness may supervene as the result of a commencing peritonitis. In other cases the symptoms of peritonitis come on in the midst of robust health; in such cases the symptoms are apt to be acute, and the attack runs a more sthenic course than when it occurs secondarily, especially in one already exhausted by disease.

The classical symptoms of acute general peritonitis are vomiting, intense pain, tenderness and distention of the abdomen; the legs are drawn up; there is moderate feverishness, with a quick wiry pulse; constipation is the rule, but diarrhœa sometimes occurs; the countenance at first wears an anxious expression, later the patient becomes hollow-eyed and the face sunken, the pulse flags, the temperature falls, and death often comes suddenly at the last.

Vomiting is almost universally present; it is usually the first symptom, and continues all through the attack; it is always aggravated by food taken. In some cases the vomiting is so persistent—first the food taken being returned, then bile, and the semi-fæcal contents of the small intestines—as to suggest some strangulation or at least some mechanical obstruction of the bowel. The abdomen is rounded and tense, in consequence of the paralytic intestines being distended with gas; the diaphragm is raised and the breathing intercostal; the amount of pain and tenderness may be trifling, especially if the patient is seen for the first time after opium has been given; in young children it is often exceedingly difficult to localize the tenderness, or, indeed, to satisfy one's self that there is any pain present.

The temperature varies, being perhaps 101°–102° F. during the first few days, falling to subnormal as collapse comes on and the heart's action fails. There may, however, be a high temperature (104°–105° F.), or the temperature may be normal or subnormal from first to last. Purulent peritonitis may be present with a normal temperature.

The state of the bowels varies: constipation is usually present, but gas is generally passed per rectum freely. There may be complete obstruction, neither flatus nor fæces being passed, the case closely simulating a mechanical obstruction from strangulation of a piece of bowel. Diarrhœa may be present in the early stages or through the whole course; this is especially so when there is some irritation about the cæcum and in suppurative peritonitis.

The urine is mostly scanty, and often contains albumen.

The fatal event is frequently sudden, the heart appearing to fail. This may happen when the patient is being moved or attempts to sit up.

The mind is generally clear from first to last, though the patient is, of course, often drowsy, from the opium given; in a few cases active delirium is present, or the patient may simply wander at times.

The following cases may be taken as illustrating the primary form of peritonitis.

Acute Suppurative Peritonitis.—John C., aged seven years. The family history was good. He had been a strong boy up to the time of his fatal illness. No cause could be assigned for his sickness. Four days before admission to hospital he complained of pain in the "stomach;" there was vomiting and constipation. On admission to hospital on the fifth day of his illness, the face wore an anxious expression, as if he was in pain; the abdomen was distended and tense, and tympanitic and tender to the least touch; his legs were drawn up; he constantly vomited dark, sour-smelling, almost fæcal stuff. The urine drawn off by a catheter contained albumen. All food and drink by the mouth were stopped, and he was given ten-minim doses of tinct. opii every second hour till three doses had been given. He passed a restless night, yet was drowsy from the effects of the opium. He gradually sank, dying on the evening of the sixth day of his illness. At the post-mortem, on opening the abdomen a few ounces of offensive pus escaped; the surface of the intestines was injected; the bowels were matted together with lymph; there was no strangulation. The cæcum and vermiform appendix were normal; there were patches of intense congestion on the mucous surface of the ileum, and a sharply-cut ulcer (not perforating), half an inch in diameter, some two feet above the cæcum. No certain cause for the acute peritonitis was found, unless it be assumed—which is indeed not improbable—that an enteritis existed in the first instance and that the peritonitis was secondary.

In the following case the symptoms closely resembled acute obstruction of the bowels from strangulation. John C., aged nine years, was in good health up to February 9, when he was injured by a blow in the abdomen, but the injury does not seem to have been very severe. He complained of pain in the belly and vomited the same evening. He continued to vomit five or six times a day till his admission to hospital (under Dr. Hutton) on the fifth day of his illness. He had passed nothing per rectum except a small stool after an enema, and it was supposed he was suffering from an intussusception. On admission, his face was flushed, the eyes sunken; the abdomen was intensely distended, the coils of distended intestines being plainly seen; he complained of paroxysms of pain in the abdomen. He vomited fæcal matter shortly after admission. There was pain on deep palpation in the right iliac fossa, but no marked tenderness. Full doses of opium were given. The next day (the sixth of his illness) it was thought advisable to make an exploratory opening into the abdomen (which was done by Mr. Wright): the intestines were deeply colored and matted together with lymph; no constricting band or invagination was detected; the wound was closed and a drainage-tube inserted. The boy gradually sank, and died suddenly the following day. At the post-mortem a general acute peritonitis was found; no cause was found, after a careful search.

In the following case, related by Sanné,[1] acute peritonitis was accompanied by diarrhœa. A boy of fourteen years, who had always enjoyed good health, was seized with shivering and headache. On the third day he had diarrhœa and pain in the abdomen, followed by vomiting, distention of the abdomen, and great tenderness; the vomiting continued, so that not only bile but also the contents of the small intestine were ejected. Death took place on the fourth day. At the autopsy a general sero-purulent peritonitis was found, without any other lesion.

Acute general peritonitis is not a common disease during infancy; Dr. West records a fatal case in an infant of seven months verified by a post-mortem; I have myself seen several such cases in children a little older, but have not been able to obtain post-mortems. In some of these cases the acute peritonitis is secondary to a suppurating mesenteric gland.

The symptoms are necessarily modified when the attack occurs in the course of other diseases or is the result of some local inflammation.

In the following case the peritonitis was secondary, occurring in the course of scarlatinal nephritis. Sarah W., aged eight years, was attacked with scarlet fever, the initial symptoms being vomiting, high fever, and rash. She was admitted to hospital on the third day; the tonsils were sloughy, there was much glandular enlargement, and high fever. The temperature varied from 100° to 101.6° F. till the twelfth day, when it reached 102.6° F. and a trace of albumen appeared in the urine; on the thirteenth day the temperature was 104° F., and only two hundred and fifty cubic centimetres of urine were passed; from the fourteenth to the sixteenth day the urine passed was only from seventy to one hundred cubic centimetres daily; urine contained fibrinous and epithelial casts; eighteenth day, vomiting, temperature 103° F., only seventy cubic centimetres of urine; nineteenth day, no urine passed, severe abdominal pain, respirations shallow and thoracic, abdomen distended and tense; twentieth day, temperature 98°–99° F., patient collapsed; twenty-first day, death. At the autopsy a general sero-purulent peritonitis was found; pleurisy of left lung; acute glomerular nephritis.

---

[1] Barthez et Sanné, Traité des Maladies des Enfants, vol. ii. p. 621.

Peritonitis in association with or secondary to pleurisy or empyema occasionally occurs: the relation which one bears to the other is not always certain. Both appear at times to owe their origin to a septic state; in other cases the pleurisy or empyema may be of some standing when the peritonitis appears, and we are forced to admit that the peritonitis is secondary to the chest-mischief. In these cases there is no perforation of the diaphragm, the extension doubtless taking place through the lymphatics of the diaphragm. Burney Yeo records a case[1] of acute purulent peritonitis secondary to pleuro-pneumonia and whooping-cough in a boy of eleven years. Eustace Smith[2] and Maude[3] also record cases of acute peritonitis secondary to purulent collections in the chest in children eighteen months and seven years old respectively.

Peritonitis coming on in the course of other diseases or spreading from the chest usually runs a rapid course, and is almost universally fatal.

Traumatic peritonitis following a penetrating wound mostly runs a rapid course, and is quickly fatal. Thus, in a case recorded by Dr. J. H. Thompson,[4] a boy, as the result of an accident, ran the handle of a hammer into the rectum; he walked a mile to the Manchester Infirmary the same afternoon, but died suddenly of collapse at eight o'clock the next morning, sixteen hours after the accident. At the post-mortem it was found that the handle of the hammer had passed up the rectum and penetrated into the peritoneal cavity; there was injection of the vessels of the peritoneum, and much lymph.

A general peritonitis following tapping of a congenital hydrocele has been recorded.

Perforative Peritonitis.—The two commonest forms are ulceration and perforation of the cæcal appendix and perforation of the ileum in enteric fever; in rare cases perforation takes place during childhood, from a tubercular ulcer of the intestine, ulcer of the stomach, or perforation through the diaphragm. To the already existent symptoms are added those of sudden collapse, fall of temperature, vomiting, and acute abdominal pain. Death usually follows within forty-eight hours. This was the case with a girl of nine years,—perforation accompanied by a sudden fall in temperature on the evening of the fourteenth day; the temperature rose again in a few hours, death taking place forty-eight hours after the perforation. The autopsy revealed a perforation three inches from the cæcum, extravasated fæces, and general peritonitis.

[4] Lancet, December 7, 1887.

Circumscribed Peritonitis, Peritoneal Abscess.—Instead of a general peritonitis taking place, a local circumscribed abscess may form, usually outside the peritoneal cavity, the pus eventually finding its way to the surface or opening into the intestine. The commonest cause of a peritoneal abscess is an inflammation around or perforation of the cæcal appendix; another not uncommon cause is suppuration of a mesenteric or retroperitoneal gland; abscesses may form in connection with tubercular peritonitis or ulceration of the ileum in tubercular disease. Abscesses in connection with the rectum, kidneys, or periosteum may involve the peritoneum. The symptoms of a local peritonitis closely resemble those of the acute general form, though they are rarely so severe or attended by collapse. There is local pain and tenderness, shivering, fever, mostly of the hectic type; there may be vomiting, but this is rarely so severe or continued as in the diffuse form. Sooner or later the local symptoms become accentuated; there is dulness on percussion over the seat of the abscess, a tumor or definite resistance may be detected on palpation, the skin becomes brawny and perhaps red, the veins on the abdominal surface are distended and tortuous. In case of a perityphlitic or appendix abscess the pus makes its way to the surface in the iliac fossa; in abscesses connected with the mesenteric glands, at the umbilicus.

The following may be taken as an example. A girl aged seven and a half years was seized with pain in the abdomen, feverishness, and vomiting; these symptoms continued for a fortnight, when she was admitted to hospital. At this time there was much pain and tenderness below the umbilicus, the abdomen was distended, temperature from 100° to 102.8° F. The next day the umbilical region was prominent, with a zone of redness; the skin gave way towards evening, and there was considerable discharge of pus. It continued to discharge pus (no fæcal matter) till the thirty-third day, when she vomited, the tenderness and pain in the abdomen increased, temperature 105° F.; the child looked anxious and pale; the symptoms pointed to a general peritonitis. On the same day, after probing the fistulous opening, a small cheesy mass came away, followed by a free flow of pus and by relief of the symptoms. The fistulous opening closed on the forty-eighth day, and she was discharged well on the seventy-third day.

In another case, that of an infant, it was noticed by the medical attendant (Dr. Noble, of Kendal), a week or two after birth, that the abdomen was more rounded and distended than natural. When five weeks old, the abdomen was intensely distended, shiny, with enlarged veins on the surface and with redness and protrusion of the umbilicus; the abdomen was resonant all over, and nothing could be felt on palpation. A few days later the skin at the umbilicus gave way and pus discharged freely. The infant a few days after died in convulsions. A large abscess-cavity was found at the autopsy, and caseous mesenteric glands.

Prognosis.—The prognosis in acute general peritonitis is always grave, recovery taking place in rare cases only. The more severe the symptoms the worse is the outlook, and when the patient has passed into the stage of collapse the case is well-nigh hopeless. Continuous vomiting, with complete obstruction of the bowels, is an exceedingly grave symptom. Diarrhœa is of evil augury. Peritonitis from perforation of the bowel is nearly always fatal; symptoms of peritonitis coming on in the course of enteric fever or typhlitis ought to give rise to the greatest anxiety as to the result. No case is, however, hopeless, and occasionally a patient who seems moribund will rally and finally recover. The duration is rarely more than a week; it may be only a few days, or even less than forty-eight hours.

Diagnosis.—The diagnosis of a general acute peritonitis when all the classical symptoms are present is not usually a matter of difficulty. The early diagnosis may be a matter of great uncertainty, as well as the diagnosis in erratic cases. Unfortunately, when the diagnosis is uncertain our treatment is often not so decided as it would otherwise be. It is especially difficult in young children, in whom it may be impossible to localize pain, and in the presence or absence of any tenderness it may not be possible to determine whether peritonitis exists or not. Long-continued vomiting from any cause, whether gastric or cerebral, produces a condition closely resembling peritonitis, though there will usually be less abdominal tenderness and the abdomen will be less distended. While there is usually much pain and tenderness in peritonitis, they may be entirely absent, or the pain may be masked by the free use of opium. While in most cases the temperature is raised a few degrees in the first three or four days of the illness, it becomes subnormal before the end comes. It may, however, be normal from first to last, even though pus is present. It is the occasional absence of some of the more prominent symptoms that makes the diagnosis often so uncertain.

In the early stages of peritonitis, assuming that the symptoms come on when the child is in good health, the pain present may be thought to be due to flatulence or dyspepsia, and the vomiting to the same cause; the presence of fever would be of little value, inasmuch as fever is so often present in children suffering from dyspepsia. The diagnosis must depend upon the severity of the symptoms: if there is constant vomiting, fluids or solids being immediately rejected, paroxysms of sharp pains, great tenderness on pressure, peritonitis is almost certainly present. The difficulty, however, frequently arises from the impossibility of determining in a young child how much pain is present. The possible presence of indigestible food, obstruction of the bowels, or the passage of a gall-stone or renal calculus must be borne in mind.

The diagnosis between peritonitis and obstruction of the bowels from a strangulation or constricting band may be very difficult, as peritonitis often produces obstruction from the paralysis of the muscular coat of the bowel and a consequent distention and kinking. In peritonitis the vomiting is rarely fæcal, and flatus may be passed per rectum; moreover, the temperature may be raised a degree or two.

Acute pleurisy, especially if it affect the diaphragm, or pleuro-pneumonia, may be mistaken for peritonitis, especially if the pain is referred to the hypochondriac regions. The presence of cough and quickened respiration and a careful examination of the chest would decide the diagnosis.

Hysterical conditions and rheumatic affections of the muscles of the abdominal wall may occur in older children and simulate peritonitis.

Treatment.—The treatment of peritonitis must largely depend upon the cause, but, unfortunately, we often have to treat our cases without knowing the exact anatomical condition which exists. As a result, we are often reduced to treating symptoms only, and perhaps have to regret, when too late, our want of courage, and to think that the patient has not had the chance that an operation would have given him; or we may perhaps believe that our meddlesome treatment has taken away from the patient his only chance. Thus, few would think that the proper treatment of a local peritonitis the result of inflammation or perforation of the cæcal appendix should be a purgative, while there can be little doubt that in traumatic or septic cases moderate purgation is useful, and that to lock up the bowels with opium from the first is a mistake.

Necessarily, the first step to treatment is diagnosis, and the history and symptoms must be most carefully gone into. In any case the preliminary steps are the same. The patient is, of course, put to bed; all food and drink by the mouth are stopped, the mouth being simply moistened with iced water. It cannot be too strongly insisted on that the distressing vomiting is certainly kept up by giving fluid or food by the mouth. Nutrient suppositories or small nutrient enemata may be given. Hot fomentations—as hot as they can be borne—should be applied over the whole abdomen, laudanum being freely sprinkled on the flannels before being applied. An ice-bag is preferred by some, but, as a rule, children resist its application. Shall we give a purgative? is a question we may not unlikely ask ourselves; the risks and the advantages alternately presenting themselves to our minds. The answer is not always easy; for it has been claimed, on the one hand, that purgation relieves the congested vessels and clears away irritating matters present in the bowels, while, on the other hand, if a local peritonitis is present around the cæcum or appendix, or there is a perforation of the bowel, a violent peristalsis is certainly risky. A Seidlitz powder or a dose of calomel is undoubtedly useful when vomiting and colicky pains are present, due to the presence of peccant matters in the bowels, or where an intestinal catarrh is present; but purgation is not to be thought of when there is local tenderness or the classical signs of peritonitis are present. When there are constant vomiting, tenderness, intense pain, distended and paralyzed bowels, purgatives can do nothing but harm. Under these circumstances opium in sufficient quantity to relieve pain and render the patient slightly drowsy must be given. Two to five minims of tinct. opii or one to four grains of Dover's powder should be given, and repeated every four hours as may be required. In older children injections of from one-twelfth to one-sixth of a grain of morphine may be substituted.

In peritonitis due to perforation of the appendix or ileum, it is needless to say, neither purgative nor enema should be allowed, for fear of the results of peristaltic action.

Free stimulation with alcohol, in the form of champagne, brandy, or whiskey, must be resorted to; if the vomiting prevents their administration by the mouth they must be given by the bowel. In the later stages little else can be done in the way of drugs or general treatment.

As soon as the diagnosis of acute peritonitis is made, the question of laparotomy—*i.e.*, opening and draining the peritoneal cavity—will probably arise. There are some surgeons who are bold enough to regard laparotomy as a hopeful method of treating acute peritonitis, and who would advocate operation at the earliest stage, believing that washing out and draining the cavity is of the first importance. On the other hand, recovery has taken place in cases where operation was strongly urged by the surgeon in attendance, but refused by the friends; while in other cases operation has been quickly followed by collapse and death. The safest course to pursue, with our present experience, is to operate only in those cases where there is good reason to believe that pus is present, bearing in mind, however, the uncertainty of our means of diagnosis. If there is hectic fever, local dulness below the umbilicus, fluctuation, extreme tenderness and œdema of the abdominal wall, there can be no doubt that an operation is urgently called for. In such cases there is a fair prospect of success.[1] These cases, however, hardly belong to the category of acute general peritonitis, which usually ends fatally in five or six days, but rather to those which run a more or less subacute course. The chances of success are greater in the older than in younger children. A certain number of cases will occur where the diagnosis is uncertain and we are in doubt whether a purulent peritonitis or only lymph is present, whether the inflammation has spread from the cæcum or has been general from the first: in these an exploratory operation is justifiable and may at times be the means of saving life.

CHRONIC PERITONITIS.

Chronic peritonitis during early life, in the large majority of cases, is tubercular: it is by no means an uncommon affection. That simple chronic peritonitis does occur is certain, as a few fatal cases with post-mortems have been reported, but, as the disease may often go on to recovery in such cases, it may be impossible to say whether it has been tubercular or not.

---

[1] See Keelley, Lancet, November 24, 1888, p. 1021.

It is difficult to say where the tubercular process originates; it may perhaps be primary in the peritoneum, but more likely may spread from a tubercular mesenteric gland or tubercular ulcer of the intestine. The presence of tubercles in the peritoneum gives rise to the effusion of lymph and serum; in some cases the one or the other is in excess. The effused lymph is slowly converted into fibroid tissue, which contracts, and consequently the great omentum becomes matted and the intestines perhaps adherent to one another. In the most severe cases the matting together of the abdominal organs is extreme, so that it is hardly possible to separate them without tearing; caseous masses and small abscesses are common. In advanced cases caseous mesenteric glands, and extensive tubercular ulcers of the intestines, as well as tuberculosis elsewhere, are associated with the chronic peritonitis.

The peritoneal covering and also the capsule of the liver and spleen become thickened. Perihepatitis as well as interstitial hepatitis may be present. In favorable cases the tubercular process comes to an end, the lymph becomes converted into fibroid tissue and lime salts are deposited; in other cases a chronic suppuration takes place and the liver and spleen become lardaceous. Occasionally the matting of the intestines gives rise to a strangulation or constriction of the bowels. The patient may succumb from a general tuberculosis.

Symptoms.—The early symptoms are usually ill defined. There is often a period of ill health, loss of appetite, coated tongue, feverishness at night, loss of flesh, abdominal pain, and attacks of diarrhœa. In children two or three years of age the ill health is generally referred to dyspepsia or intestinal catarrh. Perhaps the most significant symptom is diarrhœa, which comes in fits and starts, probably not severe, and consisting possibly of a chronic looseness of the bowels. Feverishness in the afternoon or at night with the looseness of bowels is especially significant. The abdomen is generally rounded, the small intestines being constantly distended with gas, the skin stretched and shiny. In the course of a few weeks, or perhaps longer, this distended state of the abdomen, with the fretful condition of the child, as well as his capricious appetite, excites the alarm of the friends. An examination at this time will perhaps reveal nothing but distended intestines, with very probably some enlarged veins on the surface and often a protrusion at the umbilicus. The abdomen is resonant all over, the distended bowels masking any fluid or any thickened omentum that may be present. Sooner or later, by careful palpation with the hand laid flat on the abdomen, more or less "lumpiness" will be felt, due to induration or matting of the omentum, and often more or less dulness may be detected on percussion, varying from time to time according to the amount of gaseous distention of the bowels. The percussion-note is a muffled resonance, such as would be expected from a thickened omentum backed up by distended viscera behind. The matting together of the intestines, with fluid held in the interstices between them, would naturally impair the normal tympanitic note. Frequently, perhaps usually, there is no pain on handling, or but little is complained of by the patient.

The further progress of the case is modified according to the rapidity with which the peritonitis progresses or the extension of the tubercular process elsewhere. Most of these cases are essentially chronic, lasting many months or even a year or two, and not infrequently ending in recovery. In other cases the patient becomes more and more anæmic, wasted, and flabby, the hectic fever is more pronounced, the diarrhœa more continuous and obstinate, and the patient gradually sinks, after perhaps having been reduced to a complete skeleton. On the other hand, it is by no means uncommon for tubercular meningitis to supervene and quickly bring the end.

In other cases chronic peritonitis assumes the form of a chronic ascites. After a period of more or less indefinite ill health, the abdomen is noticed by the friends to enlarge, the clothing no longer fits as it used to do, the child, if old enough to be up and about, has a peculiar gait on account of the abdominal enlargement, and a physical examination shows the presence of fluid in the peritoneal cavity. The fluid is perhaps free in the cavity, the intestines floating up when the child is in the supine position, giving a tympanitic note around the umbilicus, while there is dulness in the flanks; but with the patient on his side or on "all-fours" the lowest part gives a dull note, on account of the fluid gravitating there. In other cases there are the physical signs of matting of the omentum and intestines and also of the presence of fluid. The temperature may be normal during the whole of the twenty-four hours, there may be no wasting, and the child may appear perfectly well except for the ascites present; on the other hand, hectic, wasting, and diarrhœa are not uncommon. The case may end in recovery after many months, or, on the other hand, a more generalized tuberculosis may supervene. When recovery has taken place the fluid has been absorbed, and much of the induration disappears by a cicatrizing process.

Complications.—Tuberculosis of other abdominal organs is exceedingly common: probably in every case of tubercular peritonitis, sooner or later, other abdominal organs are affected,—the commonest being the mesenteric glands and the lymphoid glands of the intestines. A perihepatitis combined with an interstitial hepatitis sometimes takes place, and a consequent obstruction to the portal circulation. Tuberculosis of the spleen and testes is not uncommon. Tubercular meningitis or acute miliary tuberculosis is apt to supervene. Acute obstruction of the bowels may come on, or an abscess forms which probably points at the umbilicus.

Diagnosis.—The early diagnosis of tuberculosis of the peritoneum is difficult in most cases, or it is only a matter of suspicion until the physical signs of induration of the omentum or matting of the intestines or ascites are present. When ascites alone is present, a diagnosis between ascites due to chronic peritonitis and ascites due to obstruction of the portal vein has to be made. Cirrhosis of the liver giving rise to portal obstruction is very rare during childhood, and so is portal obstruction due to adherent pericardium and mediastinitis. In any given case the chances are immensely in favor of chronic peritonitis: it must, however, not be forgotten that a perihepatitis and interstitial hepatitis secondary to chronic peritonitis may be present. The abdomen should be carefully examined by palpation and percussion, to discover the edge of the liver or any indurations: the temperature is often more or less of a hectic character in chronic peritonitis, though it may be normal. The diagnosis between simple and tubercular peritonitis is often impossible. Ascites due to cardiac disease is hardly likely to be mistaken for chronic peritonitis, as the physical signs of the heart-mischief would be present and the dropsy would usually begin first in the legs. It must be carefully borne in mind that in the early stages of chronic peritonitis the symptoms are those of a chronic intestinal catarrh, and we must not jump to the conclusion that a peritonitis exists, nor, on the other hand, put it definitely out of court.

Prognosis.—In all cases of tubercular peritonitis a cautious opinion as to the final result must be given. There is always the risk that extensive caseating mesenteric glands may supervene, or tubercular ulceration of the bowel, or a tubercular meningitis. It is curious, however, how comparatively rarely extensive tuberculosis of the lungs is present. The tendency of tubercular peritonitis is towards recovery, though the risks of an acute peritonitis supervening, or an acute or subacute tuberculosis elsewhere, are by no means remote. It is certain, however, that a large number of cases completely recover, adhesions between the various abdominal organs taking place. It is important to remember this tendency to recovery, when recoveries are reported after laparotomy and when it is assumed that the patient has been snatched from certain death. The more acute the case the more unfavorable the prognosis; wasting hectic, diarrhœa, and night-sweats point to an extended area of tuberculosis.

Treatment.—As the starting-point of a tubercular peritonitis is, in the large majority of cases, to be found in a catarrh of the bowels, it is in this direction that treatment must be commenced. The presence of a chronic catarrh of the bowels in a child disposed to tuberculosis is always a source of danger, the lymphatic glands and secondarily the peritoneum becoming the seat of tubercle. In all cases where the suspicions are aroused, no time should be lost in getting the child placed under the most favorable conditions as regards hygiene: pure country air and sunlight are above all things necessary, or the child should be sent to the sea-side. His diet and clothing of course require attention. He must necessarily be kept at rest, either in bed or on a couch; in summer he should be placed as much as possible in the open air. A flannel binder around the abdomen should always be worn. The diet must be plain, consisting of moderate quantities of underdone chops; fish, fowl, and eggs can be taken; milk and cream, if they agree, should be given in moderate quantities; excess of starchy foods should be avoided, but toast and light ground-rice puddings may be given. Any tendency to diarrhœa will necessarily lead to a modification of the diet. Pain in the abdomen may be relieved by opium fomentations or belladonna applications; in the more chronic cases mild mercurial preparations, such as an ointment of the yellow oxide of mercury (twenty grains to the ounce), are useful. The medicines given must be those that assist digestive processes, such as acids and pepsin preparations, or those that are calculated to relieve the dyspepsia consequent on the intestinal catarrh, such as alkalies, bismuth, or vegetable bitters. Cod-liver oil and iodides are of value as tonics. If the fluid in the peritoneal cavity is excessive and shows little tendency to reabsorption, tapping should be performed, preference being given to a very small trocar and canula, the fluid being allowed to drain slowly away. If pus is present, incision and drainage should be resorted to, though in chronic tubercular suppurative peritonitis the prognosis is exceedingly grave. Recently laparotomy and washing out of the peritoneal cavity have been advocated by some surgeons as a routine treatment, and successful cases have been reported by Treves,[1] Lawford Knaggs, and Kelner Clarke; and the experience of these surgeons has gone far to show that the peritoneum in tubercular peritonitis is tolerant of surgical interference. In any case where hectic fever, local tenderness, and dulness suggest a collection of pus, an exploratory operation should be performed. In the more chronic cases, where the symptoms are not urgent and the child holds its own, it is wiser not to interfere, and in a fair proportion of cases recovery may be looked for.

PERITYPHLITIS, PARATYPHLITIS, PERITYPHLITIC ABSCESS.

By CHRISTIAN FENGER, M.D.

DEFINITION.

Perityphlitis, derived from *περί*, "around," and *τυφλόν ἔντερον*, the "blind intestine," strictly speaking means an inflammation of the serous lining of the cæcum. As, however, the peritoneal surfaces of adjacent organs are necessarily involved, the term is applied in a wider sense to local peritonitis in the region of the cæcum, that is, in the right iliac fossa. The term perityphlitis was first used by Puchelt in 1832, to designate inflammation in the right iliac fossa, which about that time had been brought prominently before the profession by the essays of Husson and Dance (1827) and Dupuytren, and which had thitherto been termed *tumores phlegmonosi fossæ iliacæ dextræ*, or abscess of the right iliac fossa.

The marked frequency with which the inflammation originates in the appendix made With (1879) propose to substitute the term appendicular peritonitis for perityphlitis. His idea was to emphasize, by the adjective "appendicular," the fact that the disease almost always originates in the appendix and not in the cæcum, and that the term perityphlitis is incorrect because it directs attention to the cæcum; he also wished to correct the inherited belief that the so-called stercoreal typhlitis, caused by accumulation of fæces in the cæcum, plays a conspicuous part in the etiology of the disease. Fitz proposes the term appendicitis as more appropriate, since it designates the primary essential condition that precedes and leads to the peritonitis. The majority of authors still employ the term perityphlitis, although appendicular peritonitis and appendicitis are coming more and more into general use.

The character of the resulting inflammation differs with the varying rapidity of the destruction from within of the intestinal wall, and with the virulence and quantity of the microbes invading the peritoneum. A slow invasion of less virulent microbes, or invasion of the ptomaines alone, may cause only a local plastic peritonitis, terminating in adhesions between the opposing serous surfaces of the area involved, or *peritonitis appendicularis* *plastica*, corresponding to plastic perityphlitis. If sufficient pus-microbes enter the peritoneum to make the local peritonitis terminate in suppuration, we have the perityphlitic abscess, a localized collection of pus, corresponding to the territory of the peritonitis, bounded by a line of adhesive peritonitis, which forms a barrier of connective tissue between the abscess and the general peritoneal cavity.

Paratyphlitis was introduced by Oppolzer in 1863 to designate the inflammation in the loose connective tissue behind the cæcum, in that portion supposed not to be covered with peritoneum. The name was formed in analogy with Virchow's distinction in case of organs partially covered with peritoneum, that the prefix "peri" should indicate inflammation in the peritoneum, and "para," inflammation in the tissue surrounding the portion of the organ not covered with peritoneum. Paratyphlitis, then, is a retro- and consequently extra-peritoneal inflammation behind the cæcum.

As a localization of general pyæmia, or extension of a puerperal parametritis, there is no reason why inflammation should occur oftener in one iliac fossa than in the other. When Oppolzer states that paratyphlitis often originates in the cæcum, it becomes doubtful, as will be shown later, whether the term paratyphlitis can be correctly used in this connection. Modern anatomical research tends to show that what has been described as paratyphlitis originating from the appendix or the cæcum is either a deep-seated local peritonitis—that is, perityphlitis behind the cæcum—or has at any rate commenced as such and has not until later invaded the retro-peritoneal tissue.

In conclusion, it may be said that the term perityphlitis, subdivided into an adhesive and a suppurative variety, is sufficient to designate adequately the local peritonitis originating in the appendix and cæcum.

HISTORY.

Dupuytren, as a result of observations made prior to 1820, first called attention to the connection between abscesses of the right iliac fossa and diseases of the cæcum, in clinical lectures at the Hôtel-Dieu. In 1827 Husson and Dance gave a more minute description of the disease. Perforation of the appendix as a cause of fatal peritonitis was first described by Louyer and Villermay in a contribution to the French Academy of Medicine in 1824. Within a decade the subject had attracted considerable attention, and many important contributions to its literature had been made. The excellent articles of John Burne in England, Albers and Puchelt in Germany, and Posthuma in Holland, and that of Stokes advocating the opium treatment, all threw more and more light on the pathology of the disease; but still the cæcum was believed, on account of the stercoreal typhlitis, to play the principal part, and the vermiform appendix, although Burne had already pointed out the frequency with which it was found diseased, was usually considered responsible for fatal diffuse peritonitis only. Later on, attention was called to the appendix by Toft and With, who showed that perityphlitis is almost exclusively due to a primary disease in this organ, and that the cæcum is very rarely the primary seat of disease.

Text-books and hand-books on children's diseases treated very sparingly on this subject, although perityphlitis is usually met with in youth, and although cases in children had been on record from the earliest period (Iliff, 1832). Pepper and Meigs's hand-book of 1870 was the first treatise on diseases of children in which the subject was exhaustively treated. This was followed ten years later by the excellent article of Matterstock, in which still more attention was given to the peculiarities presented by the disease in early life.

Perityphlitis, although a Dupuytren wrote its history, has naturally, as an intra-abdominal disease, been almost exclusively in the domain of internal medicine. Surgical interference in abscesses of the iliac fossa was limited to those pointing under the skin, ready to open spontaneously. The writer on internal clinical medicine has studied its symptoms, and treated it with opium,—that is, left the pus to take its course; the pathologist has carefully pointed out all the details of the cause, course, and progress of the inflammation; but it has been left to the American surgeon to place suppurating perityphlitis where it properly belongs,—in the domain of surgery. Hancock in 1848 operated successfully upon an isolated case. His advocacy of the advantages of early operation, however, met with no encouragement.

Willard Parker, of New York, first proved, in 1867, that early operation would save three out of four patients. The surgeons of this country and abroad have followed Parker with a degree of success which has brought the disease into another field and raised many questions of detail not hitherto regarded, showing conclusively that up to that time the subject had received much more attention from the American profession than from the profession abroad. Dr. R. F. Noyes in 1883 published a masterly article on the operative treatment of the disease, with a report of one hundred operations, of which ninety per cent. were from America. Fitz has contributed an excellent, exhaustive, and timely article, treating mainly of pathology and statistics. The anatomical details have received the special attention of Ransohoff, in his interesting and scholarly paper of 1888. The brilliant results of early operation by McMurtry and Sands in 1888 have made laparotomy a justifiable procedure in certain forms of the disease.

ETIOLOGY.

Arrest of fæcal matter, with consequent invasion of inflammatory microbes, being the principal cause of the lesions in the intestinal wall, the first question that presents itself is, what anatomical peculiarities make this part of the intestinal canal the seat of the lesion? Dupuytren has already directed attention to the analogy in frequency between perityphlitic abscess and perirectal abscess or anal fistula. In fact, if the rectum were an intraperitoneal intestine, anal abscess would be as fatal as perityphlitis now is.

The anatomical points in the cæcum and appendix, therefore, deserve notice. The cæcum in man is a rudimentary organ, commencing in the fifth or sixth week of embryonal life as a blind branch of the intestine, but later differentiating into a distal, narrow, longer portion, the appendix, and a proximal but wider portion, the cæcum. It is constructed on the type of the large intestine, and remains rudimentary in the carnivora and man, while in herbivorous animals it forms a large, functionally important portion of the intestinal tract, and is constructed on the plan of the small intestine. Towards the end of fœtal life the three ampullæ or sacculi of the cæcum are formed by development of the three longitudinal bands of muscular fibres, the tæniæ coli. By the enlargement of the right anterior sac, the conical shape of the cæcum is changed to its later more tetragonal form. The apex is turned more and more to the left, until at last it is close to the ileo-cæcal junction. The appendix now lies on the posterior medial side of the cæcum, partially concealed behind it (Ransohoff).

The length and breadth of the appendix at different ages have been studied by Toft. In thirty-five specimens of the appendix at the ninth month of fœtal life, equivalent to the time of birth, the average length was four and one-half centimetres, the circumference at the upper funnel-shaped portion nine millimetres and at the lower cylindrical portion six millimetres. In children of ten months the appendix was five centimetres long, and ten millimetres and eight millimetres in circumference at the upper and the lower portion respectively. In the fourth year it was six centimetres long and ten millimetres in circumference, and in the seventh year it was seven centimetres long and ten millimetres in circumference, while in adults it is ten centimetres long and thirteen millimetres in circumference; thus showing that the appendix is comparatively longer and wider in children than in adults.

The mucous membrane of the cæcum and appendix is analogous to that of the colon, proving their physiological action to be that of absorption, favoring inspissation of the fæcal matter and the formation of firmer fæcal concretions. The mucous membrane at the entrance of the appendix forms the valve described by Gerlach, which is usually developed between the ages of three and twelve years. Ransohoff found that this valve prevented injections into the cæcum from entering the appendix, which it seems is in this way to a great extent protected from the invasion of small foreign bodies. He describes a peculiar arrangement of the mucous folds of the cæcum surrounding the orifice as in a vortex, towards which there would be a natural current of the contents of the cæcum. In this way he explains why long, narrow bodies longer than the diameter of the orifice, as pins, needles, and nails, are found in the appendix.

The question of the relation of the peritoneum to the appendix and cæcum is a most important one. The appendix has an entire peritoneal covering, and a mesentery, the so-called mesenteriolum, the length of which determines the mobility of the appendix. A fold in this mesenteriolum forms the ileo-cæcal fossa of Luschka. When extensive inflammation from within outward, or perforation of the appendix, takes place, peritonitis must necessarily follow. Until recently the cæcum was described as being covered with peritoneum on its anterior and lateral aspects, but having, as a rule, a portion of its posterior surface buried in the loose retro-peritoneal tissue. Perforation in this place would not directly involve the peritoneum, but would cause the paratyphlitis of Oppolzer and other authors. Although anatomists like Luschka and Hyrtl insisted that the cæcum was covered all over with peritoneum, and even that the lower portion of the ascending colon often had a mesentery, a fact well known to surgeons in cases of hernia, it was left to Treves and Ransohoff to settle the question decisively. Treves never saw the cæcum without a mesentery, and Ransohoff after the examination of sixty-three bodies found the posterior surface of the cæcum not covered with peritoneum in only two cases. He is consequently right in stating that a retro-cæcal extra-peritoneal inflammation, a paratyphlitis, is an anatomical impossibility, for any inflammation extending from within outward, either of the cæcum or of the appendix, must cause an intra-peritoneal inflammation,—a peritonitis.

The location of the cæcum and appendix on the psoas muscle, above the inner portion of Poupart's ligament, varies according to the length of their mesenteries; in eighteen per cent. they may be found in the pelvis minor (Ransohoff). Kraussold points out that he has found the appendix in other than its usual position,—viz., behind the cæcum and the ileum, on the right or lower side of the mesentery. He has often found it along the right border of the ascending colon, point upward; sometimes down over the pelvic border or extending from behind around the ileum at its junction with the cæcum. The various positions of the appendix would tend to determine the seat of a local appendicular peritonitis, and should be taken into consideration in making the diagnosis.

The frequency with which the disease occurs in children has been noted by Demme. In a total of one hundred and twenty-seven patients from the Children's Hospital and Polyklinik in Bern there were thirty-six cases of pronounced perityphlitis, in only nine of which coprostasis caused the disease. It is well known that males are much more subject to the disease than females. Fitz out of two hundred and forty-seven cases of children and adults found the disease in eighty per cent. of males and twenty per cent. of females. Matterstock in seventy-two cases of children found the disease in fifty-one males, or seventy and four-fifths per cent., and in twenty-one females, or twenty-nine and one-fifth per cent.

The following extensive statistics of Fitz and Matterstock show that perityphlitis is most common between the ages of ten and thirty. Between thirty and forty it is a little more frequent than from birth to ten, when it is about ten per cent.

Age.	Matterstock.	Fitz.	
	Perityphlitis, 474 cases.	Appendicitis, 228 cases.	Perityphlitis, 178 cases.
0–10 years .	46 cases, 9.7 per cent.	22 cases, 9.6 per cent.	10 cases, 5.6 per cent.
11–20 " .	143 " 30.1 " "	86 " 37.7 " "	53 " 29.9 " "
21–30 " .	158 " 33.3 " "	65 " 28.5 " "	53 " 29.9 " "
31–40 " .	72 " 15.2 " "	34 " 14.9 " "	25 " 14 " "
41–50 " .	30 " 6.3 " "	8 " 3.5 " "	18 " 10 " "
51–60 " .	18 " 3.8 " "	11 " 4.8 " "	10 " 5.6 " "
61–70 " .	5 " 1 " "	1 case, 0.4 " "	7 " 3.9 " "
71–80 " .	2 " 0.4 " "	1 " 0.4 " "	2 " 1.1 " "

We have from Matterstock, in seventy-two out of his total of four hundred and seventy-four cases, statistics of the disease in children up to fifteen years of age.

The ages of the children were as follows:

Age.	Boys.	Girls.	Totals.	Age.	Boys.	Girls.	Totals.
7 months	1	. .	1	8 years	4	1	5
20 "	1	. .	1	9 "	5	3	8
2 years	. .	. .	. .	10 "	2	1	3
3 "	2	2	4	11 "	5	3	8
4 "	2	. .	2	12 "	6	2	8
5 "	3	1	4	13 "	6	1	7
6 "	. .	3	3	14 "	5	1	6
7 "	6	. .	6	15 "	3	3	6

In very young children the disease is rare, and isolated cases only are on record. The youngest I have found was reported by Demme. A girl seven weeks old was fed after the seventh day upon porridge. In the third week she became restless, and was given more porridge. In the beginning of the seventh week high fever, tympanites, and tenderness in the cæcal region were noticed, quickly followed by peritonitis and death. The autopsy showed diffuse peritonitis, most pronounced in the cæcal region. The appendix was dilated and filled with adherent, firm, solid, concrete-like fæcal masses. On microscopical examination these were shown to be a conglomerate of undigested porridge. Perforation of the appendix was not found. Matterstock mentions the case of a boy seven months old; Silbermann, a case of peritonitis in the late period of lactation, caused by perityphlitis following long-continued constipation. Matterstock and Fitz each report a case in a child of twenty months. From the third year the disease becomes more common.

Fæcal Concretions.—Mechanical injury to the mucous surface of the appendix and the cæcum from fæcal concretions plays the most conspicuous part in the etiology of the disease. Fæcal concretions are much more commonly found than foreign bodies. Matterstock has collected one hundred and forty-six cases of perforation of the appendix: in sixty-three cases fæcal concretions were found, in nine cases foreign bodies; in eight cases nothing was found, and in the remainder no cause was reported. In forty-nine cases of death from perityphlitis in children, perforations were found thirty-seven times. In twenty-seven cases concretions were found; in three, foreign bodies; in six, nothing at all, in spite of thorough investigation. Fitz found in one hundred and fifty-two cases, of children and adults, fæcal masses in forty-seven per cent. and foreign bodies in twelve per cent. Hagen attaches more importance to foreign bodies, as he observed in his cases of perforation of the appendix sixty-nine and one-half per cent. of fæcal concretions and thirty and one-half per cent. of foreign bodies.

In the appendix are found single or multiple, soft or hard, moulded masses of fæcal matter, cylindrical, with pointed ends, rarely containing a nucleus of a foreign body, as a fruit-seed, hair, bristle, etc., causing corresponding single or multiple perforations. The softer masses are normal inspissated fæcal matter, which may, however, be easily crushed between the fingers. The harder masses often have concentric layers of different colors, containing, as Albers has stated, phosphate of calcium. The same constituent was found by Smith, mixed with a small amount of carbonate of calcium. Roger, in the case of a child five years old, found diffuse peritonitis, the appendix enlarged to three times its normal size, and in its middle two perforations from two enteroliths the size of a cherry-stone, which upon examination were found to contain organic salts of the bile, and a little phosphate and carbonate of lime and magnesium, with no foreign body as a nucleus. Sands, in operating on a boy of three, found three fæcal concretions: one, nearly spherical, about a quarter of an inch in diameter, lay free in the peritoneal cavity, a second had partly escaped from an opening in the appendix and was picked out with forceps, whereupon the third one dropped from the opening.

Cæcal stones (Albers) are exceedingly rare; they are larger,—of the size of a walnut or a hen's egg,—and often have as a nucleus a foreign body, such as a piece of potato-peel or cabbage (seldom a gall-stone), surrounded by a shell of calcareous matter or triple phosphates. They generally cause obstruction of the bowel, with symptoms of ileus. Albers mentions a case of a boy of ten who, after measles, had pain in the cæcal region, and died with the symptoms of obstruction. A calcareous concretion at the ileo-cæcal valve was found to have caused the stenosis, without perforating the bowel. Bourdon observed perforation and fatal peritonitis caused by a similar concretion of hard, clay-like fæcal matter. These cæcal stones may become detached and pass by the rectum, or may after perforation be evacuated through the abscess. Habershon found in the museum of Guy's Hospital a large calculus, the size of a hen's egg, which had been removed from a sinus leading down to the cæcum (Bartholow).

Foreign Bodies.—A great variety of foreign bodies has been found, either as such, or often forming the nucleus of a fæcal concretion: fruit-stones (cherry-stones), in a five-year-old boy; ascaris, in a three-and-a-half-year-old girl (Matterstock); hairs, from the centre of a fæcal concretion (Hagen); orange-seed, in an eleven-year-old girl (Savior.) Grape-seeds and a lima bean (Bartholow) were evacuated with pus from abscesses in adults. A shirt-button (Demme) caused a perityphlitic abscess which opened into the rectum; the button was evacuated, and the child recovered. Bossard found it difficult to put cherry-stones into the appendix. How soon after its introduction into the alimentary canal a foreign body may cause perforation has been noted in some cases. Savior states that the orange which furnished the seed perforating the appendix in the case above mentioned was eaten eight days before the beginning of the disease. Demme saw a girl seven years old who had swallowed a number of glass beads, the size of a pea, seventeen to twenty days before the beginning of the perityphlitis. This apparently subsided in two weeks, but a relapse occurred three weeks later, with formation of an abscess in the ileo-cæcal region. Upon incision, pus and three glass beads escaped. The girl recovered. At autopsies foreign bodies are often accidentally found in the appendix, which have caused no apparent injury to the intestine. In Gerhardt's clinic in Jena a lead button was found in the appendix of a boy seventeen months old; Jadelot found four ascarides in the healthy appendix of a boy thirteen years old.

Ulcers.—Tuberculous and typhoid ulcers are rarely the cause of perityphlitis, as compared with the general frequency of the diseases. Fitz reports only eight cases of tuberculous and three of typhoid ulcers. Dysenteric ulcers are still more rarely found (Birch-Hirschfeld).

Traumatism.—Mechanical injuries to the ileo-cæcal region or the abdomen are rarely reported as causing perityphlitis. Cushing saw a case of an eight-year-old boy, previously healthy, whose playmates threw him down in a ditch and put stones on his stomach. He was in bed one day, at school again in three days, and received another injury while playing. Symptoms of peritonitis were seen fourteen days after the first injury. Median laparotomy was performed, with evacuation of a pint of fetid pus; death occurred next day. The autopsy revealed a perforated appendix containing a fæcal concretion in an abscess-cavity, surrounded by firm adhesions which, by giving way at one place, caused communication with the general peritoneal cavity. Homans observed perforation in a girl of eight after a fall; Maisch, in a seven-year-old boy after a kick in the abdomen; Amyot, in a nine-year-old boy after a long wagon-ride; Buchner, in an eleven-year-old boy; and Patterson, in a fourteen-year-old girl after a journey.

Overloading the Stomach.—Indigestible Food.—Burne relates the case of a boy taken sick after eating a great amount of mince-pie. Fruits with stones, as cherries and grapes, are mentioned in cases of children, Matterstock citing four cases from the literature. Oatmeal (Pepper) is said to favor the formation of intestinal concretions; so is the exclusive use of meat and fish, as by the Esquimaux in Siberia (Speck); also farinaceous food, such as potatoes (Boys de Loury).

Emetics, Drastic Purgatives, Clysmata, are assigned a part in the eti-

[illegible] by Bossard [illegible]. This can only be understood in the sense in which already a pre-existing ulcer or the scar of perforation, or an [illegible] localized lesion is [illegible] as a result of the [illegible] mechanical movements caused by these agents. The same holds good for such causes as lifting, jumping, efforts at defecation, vomiting, sneezing (Taverney).

Constipation and Intestinal Catarrh.—Bossard does not think that every little [illegible] accumulation of feces in the appendix is pathological and can of itself be a cause of perforation, since by its normal contractility even foreign bodies can be evacuated. Constipation is surely the cause in rare forms in children, but more frequently in adults (Talamon). A severe catarrhal condition of the muscles is considered by Bossard to be a much more important cause. In thirty autopsies he found in seven cases [illegible] hypertrophy of the mucosa of the appendix. Intestinal catarrh was found to have [illegible] in an elementary way by Elis.

PATHOLOGICAL ANATOMY.

Seat of the Primary Lesion.—The primary lesion is much more frequently found in the appendix than in the cæcum; in fact, the latter may be said, by comparison, to play no part at all. The early use of the expression "perityphlitis," and the so-called stercoral typhlitis, which was erroneously considered an important factor in the pathogenesis, tended to draw attention away from the appendix. Post-mortem examinations very rarely showed primary changes in the cæcum, whose walls are comparatively more resistant, [illegible], while the appendix was found to be the case in the appendix.

Changes in the mucous surface of the wall of the lumen caused by local conditions are the following: pressure-ulcers and [illegible] of the epithelium. These are the result of contact with a foreign body or [illegible] concretion, especially in the case of a mucous membrane which is the seat of a catarrhal inflammation due to other than mechanical causes. The invasion of the microbes [illegible] from the [illegible] sub-epithelial tissue causes a [illegible] inflammation. This inflammation, extending through the muscular coat into the subperitoneal tissue and peritoneum, will show the usual signs of [illegible] inflammation, [illegible] of the tissues involved. The destruction of the intestinal wall [illegible] may be limited [illegible] the way from the epithelium to the peritoneal surface according to the [illegible] penetrating [illegible] in general. [illegible] the mucous membrane and the muscular coat, [illegible] the serosa, [illegible]. [illegible], as in the case of a girl of [illegible], who had suffered for [illegible] years from disease of the bowels, that the serum had become [illegible] bands of [illegible] tissue [illegible] the [illegible] wall [illegible]. The appendix [illegible] often totally or partially transformed into a connective-tissue mass, the lumen is obliterated, and eventually the distal patent portion is dilated or transformed into a so-called retention-cyst, suppuration in which may lead to further local destruction of the wall and to perforation.

A plastic peritonitis binds the surface involved to the peritoneal surfaces with which the bowel is in apposition, and the appendix or cæcum is buried in a mass of connective tissue, sometimes thick and dense, sometimes only a movable web of fine membranous adhesions. This, the lightest and most limited form of appendicitis (Fitz), which includes With's adhesive appendicular peritonitis, is exceedingly common, and is probably never recognized clinically, on account of the lack of distinct symptoms, but is an accidental discovery on the post-mortem table. The frequency is illustrated by the investigations of Toft. In three hundred autopsies he found the appendix pathologically changed, showing signs of previous disease, in over thirty per cent.; in five per cent. there was ulceration; in one per cent., perforation. Tüngel, in the autopsies in the Hamburg Allgemeine Krankenhaus for two years, observed thirty cases of total or partial obliteration, forty-three cases of catarrhal inflammation and old fæcal concretions, in twelve cases adhesions, and in eleven cases tuberculous ulcers. Kraussold, as a result of three hundred autopsies, regards the frequency of abnormalities as given by Toft as too small; Ransohoff, on the other hand, after the examination of more than sixty bodies, found abnormalities of the appendix in eight only; he consequently thinks that, in this country at least, the estimate of the above-named authors is too high.

The more extensive inflammation which penetrates the intestinal wall, and thus gives symptoms recognizable at the bedside, is the only form of clinical and practical importance. As shown in the normal anatomy, the appendix and cæcum being provided with a mesentery, peritonitis must result when the wall of the bowel is penetrated. The intensity and extent of this peritonitis probably depend upon the extent of the perforation of the bowel and upon the amount of the intestinal contents which has penetrated into the abdominal cavity. In milder forms, where perforation is small or imperfect, with limited escape of the contents of the bowel, the circumscribed peritonitis of Oppolzer, or local appendicular peritonitis of With, is the result. In the graver forms, with sudden rupture of the diseased wall of the intestine and escape of the contents, acute diffuse peritonitis follows.

The localized peritonitis—perityphlitis proper—may be of the serofibrinous variety to a very great extent, and surround only a very small collection of pus (Aufrecht), sometimes none at all, and may terminate in recovery by absorption or resolution. Of one hundred and eighty cases of typhlitis and perityphlitis collected by Fitz, thirty-two per cent. belonged to this class. In more severe cases a localized collection of pus—the perityphlitic abscess—forms. According to Balzer, abscess-formation is much more rare in children than in adults. The seat of the perityphlitic abscess depends upon the location of the appendix and the place of perforation. When, as is most common, it extends from behind the cæcum, upward behind the ileum and beneath the lower surface of the mesentery, pointing to the left, it may have its centre on the medial side of the cæcum, if the end of the appendix is perforated. When located behind the cæcum and pointing upward along the right side of the cæcum and ascending colon, the abscess can be located in this place (Kraussold). When the appendix reaches over the brim of the pelvis minor, according to Ransohoff a very rare occurrence, the abscess may be located in the vicinity of the rectum or uterus. In the great majority of cases the centre of the abscess is behind or around the cæcum. The walls of the cavity, therefore, are, according to the location, either coils of intestine alone, or, more commonly, partly intestines and partly the posterior or external abdominal wall. The abscess-cavity, unless distended and consequently round in shape from a large accumulation of pus, may have an infinite variety of forms according to the accident of location, a condition always found in intra-peritoneal limited collections of pus; which, of course, increases the difficulty of perfect drainage. The contained pus is commonly fetid when the perforation is large enough to admit saprogenous microbes or even fæcal matter. Necrotic shreds of omentum or para-peritoneal connective tissue, or even necrotic portions of the appendix, together with gas and fæcal matter, may be found. Fitz states that pus may be found on or after the third day from the beginning of the peritonitis or the perforation.

Extension.—A perityphlitic abscess may extend or open into any of the adjacent spaces, cavities, or organs. Usually it opens into the intestine, cæcum, small intestine, or rectum. The destruction of the wall taking place from without, the opening, whether single or multiple, is funnel-shaped or terraced. The opening in the peritoneal coat is larger than that in the muscular, while the smallest opening is in the mucous coat. It may, when the perforation takes place obliquely, be valvular, so as to hinder the escape of fæces back into the abscess (Tissier). Perforation into the bowel and evacuation of the pus or pus and blood is a common occurrence. This has been regarded, from the time of Dupuytren, as a desirable event, as the tumor disappears, fever subsides, and recovery generally follows. In many cases the abscess is so small that the presence of pus in the fæces is unnoticed (Aufrecht). Spontaneous evacuation of the pus was found by Fitz in eighteen per cent. of the cases. Evacuation into the bowel is not always beneficial, as it is sometimes followed by extension of the abscess. Perl reports the case of a child of two and a half years, in which a perityphlitic tumor suddenly disappeared, but subsequently an abscess formed, with a perforation at the umbilicus leading to the intestine. Bartholow noticed, in nineteen cases of children and adults, three perforations into the bowel and three both into the bowel and externally. After perforation into the bowel new infection takes place, from the entrance of fæcal matter or a fresh invasion of microbes, followed by sepsis and death. Thus perforation into the bowel is not so salutary as was once generally supposed. Out of six cases of children, reported by Demme, three died. Kraussold has made the observation that fæcal matter, not present in the abscess-cavity at the time of operation, frequently is not seen until from four to seven days after, when defecation has taken place and renewed peristalsis has facilitated the entrance of fæces into the appendix. The abscess extends to or finally through the abdominal wall in the ileo-cæcal region, or towards the umbilicus, where (Henoch), in children, abscesses from perforated intestines generally come to the surface.

Opening into the bladder is rare. Bossard states that a fatal fæcal cystitis, or the formation of calculus with fæcal nucleus, may result. Extension of the inflammation to the ovary has been noticed by Eisenschütz in the case of a girl six years old, where the perforated appendix adhered to the right ovary, which was in a state of acute suppurative oöphoritis. Communication between the perforated appendix or the abscess-cavity and the internal iliac (Powell), or the deep circumflex iliac artery (Bryant), may be regarded as unique. Extension to branches of the portal vein is one of the features of sepsis, and a thrombo-phlebitis is ominous, as it is followed by extension of the sepsis and secondary embolic abscesses in the liver, usually with fatal result. Matterstock observed this in eleven out of one hundred and forty-six cases. Extension along the outside of the ascending colon to the liver and upward behind the latter causes a subdiaphragmatic abscess which may perforate into the pleural cavity. Bamberger has reported two cases of the former and three of the latter condition. Tillmanns, in twenty-two cases of fæcal pleural fistula, found that six, all of which were in the right pleural cavity, originated from perforated appendices. Extension through the peritoneum of the posterior abdominal wall into the retro-peritoneal tissue leads the abscess down along the psoas or iliacus muscle, or upward into the region around the kidney. In the latter case a paranephritic abscess results, in the former an abscess extending to or below Poupart's ligament, on the femur. This latter may perforate into the hip-joint (Aubry and Moore), or may perforate or extend into the perirectal tissue and point into the gluteus maximus, in the sacral or coccygeal region, as observed by Louvier in the case of an adult. Perityphlitic abscesses extending to the left side of the abdominal cavity, in the region of the spleen (Aufrecht), or the left iliac region (Bartholow), have been observed. A perityphlitic abscess opening into the peritoneal cavity will cause an acute diffuse peritonitis. This took place in six of thirty cases reported by With, and in eight of Bull's sixty-seven cases. Secondary perforation into various organs or places is more common in adults than in children. Matterstock, after the consideration of two hundred and fifty cases of adults and seventy-three of children, estimates the proportion as thirteen to five and a half.

The existence of paratyphlitis, paratyphlitic abscess, or inflammation in the post-cæcal or retro-peritoneal tissue in connection with the cæcum and appendix, is disputed. Oppolzer believes that it often originates from the cæcum from a parametritis *in puerperium,* or as a localization during pyæmia, while it rarely originates from a local peritonitis or a psoas abscess. Of course this discussion deals only with those paratyphlitic abscesses originating in the cæcum and appendix. Most of the modern authors, because of the lack of peritoneal investment to the cæcum and appendix, deny the possibility of a primary paratyphlitic inflammation in this connection. Sands, however, asserts that most of these abscesses are extraperitoneal. This difference in opinion is probably unimportant, as a local peri-appendicular suppuration, originally of necessity intraperitoneal, when located behind the cæcum will quickly extend into the para- or post-cæcal tissue, where there is no barrier either upward to the kidney or downward to Poupart's ligament (König). Consequently the abscess is, anatomically speaking, paratyphlitic. This is the most common extension of the appendicular peritonitis. When Oppolzer attempts to give a distinct differential diagnosis between paratyphlitis and circumscribed peritonitis, it must be remembered that such a distinction is pathologically false. It would nevertheless be clinically justifiable if any important consequences as to prognosis or treatment could be deduced therefrom, but this is not the case.

Acute diffuse peritonitis, the gravest consequence of perforation of the appendix and cæcum or of the perityphlitic abscess, occurs as a result of the escape of a sufficient quantity of microbes into the peritoneal cavity, and divides with general sepsis the percentage of mortality. The exudate varies as in other forms of peritonitis ; sometimes a fibrinous exudate with no fluid, at other times accompanied by a copious amount of fluid. The fact is characteristic that the exudate is usually more copious in the ileo-cæcal region, as the inflammation begins at this point. Even when large openings into the appendix are present, fæcal matter or air rarely escapes into the peritoneal cavity, as is the case in perforative peritonitis from other parts of the intestine. This is probably due to the fact that the appendix seldom contains much air or fæces, to escape through the opening. Perforation of the appendix is often followed by diffuse peritonitis. Thus, Volz reports this in thirty-one out of thirty-nine cases, Cless in seven out of eight cases. With reports thirty cases of appendicular peritonitis, of which sixteen were diffuse ; twelve of these resulted fatally ; in two, diffuse peritonitis was caused by perforation of the abscess into the peritoneal cavity.

SYMPTOMS.

It is difficult—almost impossible—to give a well-defined symptomatological description of perityphlitis, because there is nothing typical in its course. The inflammation may cease at any point, from its origin in the mucous membrane to its diffusion to the whole peritoneal cavity, or its secondary extension to adjacent or remote parts of the body. At the same time the unity at the starting-point is rather constant, and the pathology, always in view, furnishes a guide through the great variation in symptoms and course. Albers divides the disease into prodromata followed by two stages. Cless classifies the symptoms into premonitory symptoms, symptoms of the beginning of the disease, and symptoms of the further course. Bossard distinguishes between the symptoms of three forms of the disease, —a light, a median, and a severe form. With, keeping the pathology more in view, makes the classification of symptoms as follows: first, the symptoms of an adhesive appendicular peritonitis, corresponding to the premonitory symptoms; second, a local appendicular peritonitis with or without abscess, corresponding to the light and median forms of Bossard; and, third, a universal appendicular peritonitis, corresponding to the fatal cases of Bossard's severe form. With's division of the symptoms is manifestly the most exact and scientific.

Prodromal symptoms, according to Matterstock, are more common in children than in adults. In thirty per cent. of his cases of children he found that the premonitory symptoms preceded the disease by days, weeks, or even years. These consisted of mild or severe attacks of colicky pains in the cæcal region, a little tenderness localized here, nausea, and occasional vomiting, constipation alternating with diarrhœa, followed by flatulence and painful tenesmus. Such attacks may have kept the patient in bed for a day or two, or may have passed almost unnoticed. Adults sometimes state that these slight disturbances were exactly similar to the initial symptoms of the final, severe, or fatal attack of the disease (With). It is evident that in the case of smaller children it is almost impossible to recognize these premonitory symptoms in their true light.

The symptoms of local appendicular peritonitis or perityphlitis are: Sudden violent pain in the region of the cæcum, or, more rarely, in the epigastric region, the patient having been in apparent good health; the patient cannot walk nor stand straight, but bends forward and to the right, and lies down with the right leg slightly flexed on the hip. The pain may be general, all over the abdomen, and not be localized in the cæcal region for several hours or days. Coughing or deep inspiration increases the pain, as does the effort to extend the right leg. The pain makes the patient keep quiet in bed, or may by its severity, notwithstanding the tenderness and pain, cause him to move restlessly around in bed, in the effort to find a position in which there will be relief from the pain. With says that this occurs usually in the cases in which the inflammation remains localized. A copious meal may directly precede the pain. There is vomiting, first of the food-contents of the stomach, later of bile: sometimes there will be only a single emetic effort, but not uncommonly there will be several, accompanied by borborygmi and flatulence. Clysmata or injections may induce the vomiting, which is, as a rule, speedily subdued by opiates. Symptoms of ileus, and especially fæcal vomiting, are rare. The appetite is lost entirely, but the patient is usually thirsty. An initial chill is more rarely met with in children than in adults. Fever is generally an early symptom, sometimes preceding the pain, the temperature ranging from 101° to 103° F., with a remission in the morning. The pulse is usually accelerated, ranging from 90 up to 130. Sometimes a high pulse is observed with low temperature. The general expression is that of a severe illness. Light icteric discoloration of the skin and conjunctiva is sometimes seen. In smaller children convulsions, and delirium in the milder forms, are common. The urine may be scanty and saturated, and urination painful, even when no peritonitis has as yet reached the region of the bladder. The retention of urine, and pain in the region of the bladder and external genitals, may divert attention from the actual seat of the disease. Constipation is less common in children than in adults. Diarrhœa is frequently present, either alone, or alternating with constipation.

The abdomen is either tense and flat or, later on, slightly tympanitic. There is general tenderness on pressure, most pronounced in the ileo-cæcal region; or the tenderness may be localized in the latter place. The increased tenseness in the ileo-cæcal region is often accompanied by prominences from local accumulations of gas in the intestines, or later from peritoneal exudates. A tumor in the cæcal region may soon appear, smooth or nodulated, elastic or firm, immovable, and increasing to the size of a fist. Contraction of the abdominal muscles frequently prevents palpation, so that the location of the tumor, if deep-seated, cannot be determined except in narcosis. Later on, when the tenderness has subsided, the tumor may be easily made out. Tense or inflated ansæ of intestine may be felt in or near the ileo-cæcal region (With). Pressure on or inflammatory irritation of the crural nerve or the crural plexus may cause radiating pains, formication, or numbness in the leg and in the region of the genital organs. Pressure on the iliac vein may produce œdema of the leg. Percussion is usually dull tympanitic, from exudates or tense or inflated ansæ of intestine, seldom completely dull, in the cæcal region. The rest of the abdomen is tympanitic. Respiration is often accelerated, embarrassed, or superficial, on account of pain or of pressure on the diaphragm.

Course.—In the milder cases the vomiting and paroxysmal pain cease after a few days, the temperature gradually goes down, the tension in the right iliac fossa subsides so that it ceases in two or three weeks, and the exudate is absorbed. In more severe cases the symptoms persist longer, but gradually disappear. Alvine evacuations become regular, after free passage of wind and offensive fæces; the appetite returns; meteorism disappears; the tumor subsides, though for months a gradually decreasing deep-seated induration, the pericæcal cicatrix, may be felt. Slight attacks of pain or uneasiness in the cæcal region, called forth by overeating or bodily exertion, may remain for a long time, and act as a warning of relapse. A sudden subsidence of the alarming symptoms is seen when spontaneous evacuation of the abscess into the intestine takes place: the appearance of the patient is entirely changed in a few hours; the vomiting stops; the fever disappears; sleep, accompanied by perspiration, comes on. Copious passages from the bowels, mixed with pus, sometimes streaked with blood, announce the breaking of the abscess. The tumor disappears at the same time, or subsides so as to leave only a deep-seated resistance, with little or no tenderness on pressure.

In more severe cases of localized perityphlitis the symptoms persist: there is no evacuation of the abscess, no sudden subsidence of the symptoms; but, after a more or less pronounced remission, due to the limitation of the inflammation, a further exacerbation sets in, due to pyæmic localizations in remote organs. Pyothorax, pericarditis with dyspnœa, thoracic pain, higher temperature and increased prostration, extension of the septic inflammation to the retro-peritoneal tissue, invasion of the paranephritic region and pararectal tissue, perforation of the diaphragm, causing a pyopneumothorax, usually if not exclusively on the right side, perforation of the bladder, with the symptoms of cystitis,—all these complications protract the disease and make the patient remain in a prolonged state of danger until, according to the gravity of the lesion, death from sepsis or exhaustion, or a slow and often imperfect recovery, ensues.

A sudden onset of the grave symptoms,—intense diffuse abdominal pain, collapse, frequent pulse (from 130 to 160), low or exceedingly high temperature (from 105° to 106° F.),—brought on by a passage from the bowels, a fit of coughing or laughing, or without any such cause, while the patient is in apparently good condition, means perforation of the abscess into the general peritoneal cavity, which, unless immediate operative interference is resorted to, will terminate fatally in a short time.

Finally, the perityphlitic abscess may be well encapsulated; no acute sepsis or perforative peritonitis sets in, but the abscess works its way slowly to the surface through the abdominal wall,—often at the umbilicus in children, or down the femur,—or points in the lumbar region. Fever usually slight, remittent, with evening exacerbations, loss of appetite, persistent tenderness and tumor, gradual loss of strength and weight, are indicative of this condition. Operative interference should at this time avert the ever-present danger of sudden fatal extension of the disease.

The severest group of cases, the diffuse acute perforative peritonitis from the appendix or cæcum, commences with sudden pain, extending rapidly all over the abdomen. The pain is often extreme, excruciating, so that the patient cries out loudly, and the slightest touch to the abdomen is intolerable. He hardly dares to draw his breath, twists together or draws up the legs, and at last nearly faints or has an attack of convulsions. There is immediate collapse, with cold clammy perspiration; the pulse ranges from 90 to 140, strong at first, later small and compressible; temperature from 100° to 105° F. The vomiting, at first of food, soon becomes bilious, but rarely stercoraceous. Opiates have little effect on the pain and vomiting. The pain occasionally intermits, but quickly returns, and requires a larger dose of the narcotic. The vomiting, often accompanied by persistent hiccough, usually increases in frequency, and may last until the end, or, rarely, may abate. Foul eructations occur, even in cases where the vomiting is not fæcal. Constipation or diarrhœa may be present; the latter often becomes very copious towards the end (Pott). Tympanites, which is not present at first, usually develops rapidly, until the abdomen is distended like a drum, with tense and shining skin. Coils of distended intestine may show through the abdominal wall. The tumor cannot be felt, even before the tympanites is developed, as no localization of inflammation has yet taken place, or as a presenting abscess has emptied into the abdominal cavity. There may be no fulness in the ileo-cæcal region (Pepper). The urine is scanty, saturated, and shows traces of albumen. The urinary tenesmus and frequent urination or retention are due to pericystic inflammation. Delirium and convulsions are not uncommon in the later stages of the disease. Death takes place from collapse, rarely in from six to twelve hours; usually, however, the disease lasts from one to three days, seldom longer. Recovery is very infrequent.

When perforative peritonitis occurs in infants during the period of lactation, they become restless, will not take the breast, vomit repeatedly, have profuse diarrhœa, meteorism, and tenderness of the abdomen, with frequent respiration, followed by collapse and death. If the disease lasts more than a few days a rapid and characteristic loss of weight, up to one hundred and eighty grammes daily, occurs (Silbermann).

Review of Single Symptoms.—*Pain.*—Sudden intense pain is the most constant symptom of perforation of the appendix and cæcum, and is present in eighty-four per cent. of all cases (Fitz). The pain is less acute and severe in the perityphlitis that remains localized, or where the perforation of the appendix is imperfect. In children it is almost always present, and, if localized in the ileo-cæcal region, important. Fitz gives the following table of localization of pain in appendicitis and perityphlitis:

LOCALITY.	APPENDICITIS.	PERITYPHLITIS.
Right iliac fossa	48 per cent.	60 per cent.
Abdomen	36 "	34 "
Hypogastrium	5 "	0 "
Umbilical region	4 "	2 "
Epigastrium	2 "	4 "
Stomach	1 "	0 "
Hepatic region	1 "	0 "
Left iliac fossa	1 "	0 "
Right hip and groin	0.5 "	0 "

Smaller children show uneasiness and rarely cry out loudly: usually they cry intermittently. As a rule, in children the pain is often an early symptom, even in attacks preceding the actual inception of the disease (Matterstock). Pain at first slight, but gradually increasing for a few days before the patient goes to bed (Homans's case), may signify local perityphlitis. Pain more acute at first, increasing, and uncontrollable by opiates, may mean spreading general peritonitis. Pain diffuse in the beginning, later localized to the cæcal region, indicates local peritonitis. Disappearance of pain in the diffuse peritonitis, when the other grave symptoms persist and collapse sets in, is an indication of early fatal termination. Sudden intense pain as a symptom of the beginning of a more extensive peritonitis occurred, according to Fitz, in appendicitis and perityphlitis respectively, as follows:

TIME.	APPENDICITIS.	PERITYPHLITIS.
First day	67 per cent.	75 per cent.
Second day	8 "	16 "
Third day	20 "	3 "
Fourth day	3 "	6 "
Fifth day	2 "	0 "

Vomiting is an almost constant symptom in children. It was present in all of Pepper's thirteen cases, and was absent in only two of Matterstock's seventy-two cases. It is not so constantly present in adults, as it was observed by Fitz in only fifteen cases of appendicitis and in forty-four out of two hundred and nine cases of typhlitis and perityphlitis. This difference may be accounted for by the liability of children to vomit on slight provocation, as compared with adults. Vomiting was stercoraceous in none of Pepper's cases and in one only of those tabulated by Matterstock (Volz's case). Initial vomiting is more constant and copious in the cases of localized pericæcal peritonitis with final recovery than in the severer cases terminating in rapidly-spreading general peritonitis (Pepper).

Constipation or Diarrhœa.—While in adults the bowels are usually constipated, diarrhœa is often observed in children. Matterstock found diarrhœa in 33.3 per cent., constipation in 46.6 per cent., alternating constipation and diarrhœa in 15.5 per cent., and the normal alvine evacuations in 4.5 per cent. only. Pott observed that children were more liable to diarrhœa than to constipation, and that in the last stage of fatal cases there were violent liquid evacuations. Silbermann noticed profuse diarrhœa in children at the stage of lactation in diffuse peritonitis. The evacuations towards the end of fatal cases are often of a peculiarly fetid odor.

Tumor.—It is important to distinguish between simple tension of the abdominal muscles over the iliac fossa and a palpable tumor. According to Gerhardt, it is less common to find a tumor in children, because the inflammation is more liable to spread to the greater portion of the peritoneum. In nineteen cases recorded by Pepper, of children under fifteen years of age, a distinct tumor could be felt in three cases only. It is possible, however, that the use of an anæsthetic would enable us to distinguish a tumor more often. Fitz has attempted to tabulate the day of the disease when a distinct tumor can be felt, in both children and adults. Out of ninety-two cases, the tumor was felt on the first day in five, on the second in nine, on the third in twelve, on the fourth in ten, on the fifth in seven, on the sixth in eleven, on the seventh in eight, on the eighth in eight, on the ninth in eleven, and on the tenth in eleven cases.

Percussion.—Dulness of percussion may be found when the exudate is superficial; it may be absent when the exudate is covered by distended loops of intestine, or when intestinal gases have invaded the area of inflammation. The date of its appearance, as stated by Fitz from thirty-seven cases, was on the first day in two, on the second in two, on the third in eight, on the fourth in nine, on the fifth in three, on the sixth in two, on the seventh in two, on the eighth in five, on the ninth in one, and on the tenth in three cases. Accumulation of gases in the free peritoneal cavity, causing disappearance of dulness of the liver and spleen, is rarely seen, and is often prevented by adhesive peritonitis in the upper half of the peritoneal cavity. Again, dulness of the liver may be absent on account of intra-intestinal accumulations of gases,—that is, tympanites. Larger accumulations of liquid exudate in general peritonitis may exist without any perceptible dulness of percussion, the symptom being masked by overlying tympanitic loops of intestine.

Temperature usually ranges between 100° and 102° F.; With has once observed a temperature of 106°. The fever is atypical; in localized inflammation with final absorption it is often irregularly remittent. Armand Paulus observed a temperature of 104° F. in the case of a child who recovered; usually it does not exceed 102°. A gradual fall in temperature is the rule; a sudden fall is noticed only in cases where a sudden evacuation of exudates by operation or perforation into the intestine has taken place. Sands saw the temperature fall from 101.6° to 98.5° F. within an hour after laparotomy and remain below 100° or 99° during convalescence. Sudden and repeated rise of temperature during the course of the disease signifies the invasion of either a new territory of the peritoneum or of distant organs by septic material, embolism, or abscesses of the liver. In the latter case rigors may be seen repeatedly. Initial rigors are not very common in children. Sudden fall in temperature, with frequent, weak pulse and symptoms of collapse, may mean perforation and diffuse peritoneal sepsis. Even in lighter cases in children the temperature may rise comparatively higher than in adults, on account of the greater variability of the bodily temperature in early life (Matterstock).

DIAGNOSIS.

Previous attacks of pain or inflammation in the cæcal region call attention to the appendix and cæcum. Relapse was found in eight per cent. of children's cases by Matterstock, and in five out of thirty cases of adults. With found that symptoms of his "adhesive peritonitis" had preceded the disease for from two months to ten years. It is natural that the lighter symptoms in children, the slight colicky pains and vomiting lasting only a day or two, should be overlooked, or regarded as unimportant. Thus, only the more severe or repeated localized inflammations in the cæcal region in children can be of any aid in diagnosis.

Stercoreal Typhlitis, coprostasis in the cæcum or ascending colon, is said to be much more common than perityphlitis (Fitz). This statement applies to adults, but in children constipation is more rare: Demme in thirty-six cases of typhlitis and perityphlitis found coprostasis in only nine. In stercoreal typhlitis there is a history of constipation for some time preceding the attack, and this may lead to vomiting, convulsions, pain, and even fever (Matterstock) for a day or two. The tumor, however, has a doughy feel, is movable, and less painful; fæcal masses may be felt in the descending colon and in the sigmoid flexure; as a rule there is no fever, as there is no inflammation; and a laxative causes the speedy disappearance of the tumor, as well as of all the symptoms.

Invagination—Strangulation.—The symptoms may be similar (Gautier). In invagination bloody evacuations in children under one year of age are common. The obstinate constipation, location of the tumor in the left side of the abdomen, mobility of tumor, absence of fever, all aid in the differential diagnosis. The pain is not intense nor localized in the iliac fossa. In internal strangulation the absence of tumor and lack of tenderness of the abdomen are of importance. Fæcal vomiting is common in the later stages of obstruction: it is never seen in perityphlitis, and rarely in general peritonitis.

Perinephritic Abscess will usually be accompanied or preceded by some abnormality in the urine. Passage of a renal calculus (renal colic) is characterized by absence of tumor, demonstrable in narcosis, and is not accompanied by fever, but there are sometimes blood or concrements in the urine.

Psoas Abscess, which might be mistaken for chronic perityphlitis or iliac abscess, is less painful, more diffusely fluctuating, with little or no rise of temperature. It has no acute onset. There are no symptoms pointing to the intestinal tract, and there is no peritonitis. A careful examination of the spinal column or iliac bones, with the symptoms characteristic of diseases in this locality, will make the differential diagnosis comparatively easy.

Hip-Joint Disease.—Gibney reports four cases of perityphlitis in children which were brought into the hospital and diagnosed as hip-disease,—one of which was treated by extension with weight and pulley for nearly two weeks. As the flexion of the thigh in the hip-joint and pain on movement are due to inflammation in the iliac fossa, the use of an anæsthetic will clear up the diagnosis, by showing that movement in the hip-joint is unimpaired. In acetabular tuberculosis with early perforation into the pelvis, and in intrapelvic abscess, the tumor is near Poupart's ligament and lower down than in perityphlitic abscess, which is located near the anterior superior spine of the ilium.

Rectal Insufflation of Hydrogen Gas.—A valuable aid in diagnosing perforation of the appendix or cæcum, and its communication with either a localized abscess-cavity or the general peritoneal cavity, may be found in the rectal inflation by hydrogen gas, as advised by Senn. He employed the test in a case of perityphlitis in a middle-aged man. No operation was found necessary, and the patient recovered. In case the gas should enter the peritoneal cavity, immediate laparotomy would be indicated.

PROGNOSIS.

The gravity of perityphlitis depends entirely upon the extent of the septic inflammatory process. If the inflammation remains localized to a limited area of the peritoneal cavity, and does not extend through the vascular system to distant organs, the prognosis is favorable. Acute extensive perforation of the appendix or cæcum, with copious invasion of the peritoneal cavity or retro-peritoneal tissues, and rapidly-spreading septic inflammation, is almost always fatal. It is necessary to bear in mind that the disease is always dangerous, as an apparently slight case may at any moment, and especially under inappropriate treatment, become an extremely grave one. It is difficult and almost impossible, therefore, to give a reasonably certain prognosis in any given case. The statement of Bauer, Bamberger, and others that simple perityphlitis, especially if of traumatic origin, has a good prognosis, and that the prognosis becomes grave in all cases of perforation, is of little assistance to the physician at the bedside, as an exact diagnosis of perforation or its extent is impossible.

The mortality, as derived from the statistics, varies according to the selection of the cases or their arbitrary division into certain clinical groups. Volz had thirty-nine fatal cases out of forty-nine; Bamberger, only eighteen out of seventy-three; Bull, thirty-three out of sixty-seven; Matterstock out of nine hundred and seventy-seven cases had two hundred and ninety-four deaths, or thirty per cent., and six hundred and eighty-three recoveries, or seventy per cent.; With had thirty cases, with twelve deaths. In adults and children, therefore, the mortality is more than thirty per cent. The prognosis in children is, according to Matterstock, even more grave. Of seventy cases forty-nine died and twenty-one recovered, a mortality of seventy per cent. When Demme, on the other hand, records thirty-six cases of typhlitis and perityphlitis with twenty-seven recoveries and nine deaths, it must be considered that an unknown number of the lighter cases may have been simple coprostasis in the cæcum. In children sex makes no difference as to the mortality. Matterstock remarks that seven out of ten cases are fatal, whether the patients are boys or girls. Young children have less power to resist the disease than older ones. Out of twelve patients below the age of six, eleven died. Between six and ten years the prognosis was more favorable,—twenty-four cases with fifteen deaths. Between the ages of ten and fifteen the mortality seemed to increase, as out of thirty-four cases twenty-three were fatal.

When a diffuse peritonitis develops immediately after the perforation or first onset of the severe symptoms, the prognosis is almost uniformly fatal. With reports fourteen cases of universal appendicular peritonitis, with two recoveries and twelve deaths. If the perityphlitis becomes localized but suppuration takes place,—that is, the abscess forms,—the prognosis depends upon what course the abscess takes. If it opens into the general peritoneal cavity, a fatal diffuse peritonitis results (With, two cases). Evacuation of the abscess into the cæcum is more favorable: Bull gives ten cases with nine recoveries. Demme reports less favorably, however, in children: out of his six cases three died. Evacuation into the rectum justifies a good prognosis (Bull). Perforation into the pleural cavity, causing empyema, is usually fatal, and, even if a fæcal fistula forms (Tillmanns), death results later from chronic sepsis or exhaustion. Perforation into the bladder is fatal in one-half the cases (Bull). Evacuation through the abdominal wall, which was considered by Dupuytren to give a grave prognosis, is now looked upon in a different light, when a direct outlet for the pus is secured at an early stage of the disease. It may be justly considered a triumph for surgical interference when out of one hundred operations recorded by Noyes the mortality was only fifteen. The result is different when the abscess is left to burrow its way out through the abdominal walls, destroying tissue in its course. Of twenty-eight cases collected by Bull eleven were fatal. Pyæmia caused death in six out of sixty-seven cases (Bull).

The length of time between the onset of the severer symptoms and death has been noted by Fitz, who, in a series of one hundred and seventy-six cases, found that thirty-four per cent. died within the first five days, fifty-six per cent. within the first week, thirty-one per cent. in the second, and only four per cent. in the third. The prognosis is uniformly favorable in the adhesive or plastic appendicular peritonitis; but it must be remembered that after months or years a relapse may occur in the shape of an acute fatal form of the disease. In the local appendicular peritonitis the prognosis is favorable when the acute symptoms subside in a few days, when pain and tenderness become limited to the iliac region, and when the tumor remains small and gradually diminishes as the exudate, whether fibrinous or purulent, is removed by absorption. We must bear in mind, however, that even the smallest induration around the appendix or cæcum is a source of constant danger, and that the greatest care in diet and regimen is necessary to avoid the possibility of a rekindling of the dormant inflammation, the renewal and extension of which might prove fatal at any time.

TREATMENT.

Prophylaxis.—As the disease usually commences unexpectedly in previously healthy persons, it is impossible to do much to prevent an attack of perityphlitis. Regulation of the diet of children, so as to prevent the accumulation of indigestible substances in the appendix or cæcum, should be taken into consideration. Digestive disturbances, especially when accompanied by colicky pains in the iliac region, may give warning of a coming attack. The utmost care should be taken in regulating the diet and the whole regimen of children thus affected. Over-eating, over-exertion, exposure of any kind, should be avoided. A careful rectal and abdominal examination, in narcosis if necessary, should determine whether any induration has formed around the appendix, that the care and precautions so essentially necessary may be resorted to.

The treatment of a developed perityphlitic inflammation is as yet in some essential points a matter of controversy. Morton insists on the division of the disease into a pre-purulent and a post-purulent stage. In the first, medical treatment is resorted to; in the second, operative measures are employed. In the pre-purulent stage the main controversial question is whether the bowel should be evacuated when the constipation exists, or whether absolute rest of the intestines should be aimed at. If a certain diagnosis can be made between stercoreal typhlitis and perityphlitis, the question is easily solved, and cathartics or clysmata will be as beneficial in the former as opium or morphine in the latter case.

Opium in large doses is recommended by Stokes and Graves, who give children one-fourth of a grain every hour as long as there is general tenderness over the abdomen. Volz strongly insists upon the opium treatment, and warns against cathartics and enemata. It is generally admitted that the great mortality which existed at the time of Volz has been considerably lessened in later years by the opium or morphine treatment. Matterstock advises absolute rest of the intestinal canal in all cases where even a slight tenderness and swelling exist in the ileo-cæcal region, and says that, although the disease may appear to be insignificant, it must be combated most energetically, by absolute rest, liquid diet, and opium in large doses. He cannot warn too earnestly against any attempt to relieve constipation by cathartics or clysmata. Hydrate of chloral is recommended by Silbermann, for young children, in preference to morphine. He gives a teaspoonful every two or three hours of a one- to three-per-cent. solution.

Purgatives.—Among modern authors, Morton insists that salines and enemata should be employed in the early stage of the disease, to keep the inflamed intestine free from accumulations of gas and fæces. Pepper recommends liquid citrate of magnesia, repeated at short intervals, or repeated doses of calomel until the bowels are opened. With, on the other hand, while admitting the usefulness of laxatives in stercoreal typhlitis and the early stage of typhlitis, warns against their use in the early stage of appendicular peritonitis or perityphlitis, basing his argument upon the fact that the twelve fatal cases of his series of thirty had all been treated at the beginning of the disease with castor oil or enemata, and all died from diffuse peritonitis. All authors agree that purgatives or enemata must not be employed in the developed, acute stage of a local or general appendicular peritonitis or perityphlitis. When the patient progresses favorably, resolution is taking place, and pain and tenderness have disappeared, mild laxatives, alone or combined with opiates, are recommended. Pepper gives the following prescription:

℞ Pulv. opii, gr. ii to iii;
  Ext. colocynth., gr. xii to xviii.
Misce.
  Ft. mass. Div. in pil. xxiv.
One pill every three to four hours until action of bowels.

Enemata.—Monti advocates irrigation of the intestines with water or drastic remedies at the beginning of the disease. Balzer recommends clysmata when constipation exists. Pepper uses a tepid non-irritating enema. Matterstock will use enemata only in the later stages of the favorable cases when, as is rarely the case, spontaneous passage of the bowels has not taken place after the discontinuance of the opium.

Local Depletion or Counter-Irritants.—In the acute stage an ice-bag or hot fomentations are applied over the iliac fossa. Matterstock recommends a small ice-bag suspended from a frame, so as to avoid pressure on the abdomen. With believes that application of cold,—ice-bag or wet towels,—although it lessens pain, protracts or prevents the formation of adhesions around the place of perforation. He therefore prefers hot applications, which seem rather to favor a plastic peritonitis. Frequent applications of mustard plasters or turpentine stupes may allay pain. Bull and Balzer use leeches. Blisters are recommended by Balzer. If the tumor disappears slowly, applications of blisters or tincture of iodine are useful. Vomiting is relieved by ice or carbonated drinks or by subcutaneous injections of morphine.

The diet in the acute stage must be liquid, given in small quantities at short intervals. Later on, when the pain and acute symptoms have subsided, solid food may gradually and cautiously be given.

The convalescence must be watched with the greatest care, as relapse is always to be looked for, and as intestinal disturbances on slight occasions are common reminders that the inflammation is only dormant and may be aroused at any time. On this account, the diet must be watched carefully for a long time, the bowels kept regular, and no fæcal accumulations allowed to take place. Violent bodily exercise, jumping the rope, gymnastics, children's games involving over-exertion, exposure to cold, cold baths, swimming, etc., must all be avoided.

The perityphlitic abscess, or, as it is termed by Morton, the post-purulent stage of perityphlitis, is rapidly passing from the domain of internal medicine into that of modern surgery. There can be no doubt that spontaneous resolution of an abscess may take place; that in a large number, probably in the majority, of the thirty-two per cent. of Fitz's cases in which resolution was the outcome of perforating appendicitis, pus was present. Consequently, perityphlitic abscess may as yet be claimed to some extent by internal medicine for conservative treatment; but modern surgery seems to have proved that it has it in its power to diminish the mortality of the disease. It is therefore timely, in closing the discussion of perityphlitis, to take up the question of its surgical treatment by operation.

OPERATION.

Introductory Remarks.—Abscesses of the right iliac fossa had been incised before the days of Dupuytren, when fluctuation made the presence of pus certain, on the same indications as abscesses in general. The opening of a perityphlitic abscess after the pus has penetrated the abdominal wall and become subcutaneous should not be termed an operation for perityphlitis. The increasing knowledge of the pathological details of the course of the disease, the dangers apt to arise during its course at a period long before fluctuation could be detected, and the cases where, according to the anatomical condition, fluctuation would not be present, gave an impulse in the direction of early operation when either the localized peri-cæcal or peri-appendicular collection of pus had been diagnosed by the presence of a tumor or swelling or local tenderness and the other symptoms, or where general peritonitis from perforation or other causes had set in. We thus distinguish between the operation on localized suppurative peritonitis—that is, perityphlitic abscess—and the operation for diffuse perforative peritonitis.

Operation for Perityphlitic Abscess.—The first object of operative interference in such cases is to evacuate the pus by incision, or, in addition to evacuation, to attack the primary cause or seat of the disease, the perforated appendix or cæcum, in order to close the perforation in the intestine. The first of these indications was naturally the first to be acted upon. The first operation of this kind was made by Prof. Willard Parker in 1843. As his second case was not published until 1867, it may be said that Dr. Hancock, of London, who operated in 1848, and advocated the operation in the same year in the London *Medical Gazette*, was the originator of the operation. Hancock's proposal was not adopted, however, and the old conservative method was persisted in until 1867, when Willard Parker reported four cases, with three recoveries, treated by incision above and parallel with Poupart's ligament to the transversalis fascia, which was then divided upon a director and the pus evacuated. Prior to Parker's article, Gurdon Buck advocated operating before fluctuation, by making an extraperitoneal outlet for the matter below the outer half of Poupart's ligament, so as to get behind the iliac fascia and thus avoid the peritoneum,—the operation being almost subcutaneous. Dr. Parker's article and advocacy had such an effect upon early incision that Dr. Noyes in 1882 was able to report one hundred and nineteen operations, with a mortality of only about sixteen per cent. How little the operation had been resorted to outside of the United States may be seen from the statement of Matterstock in 1880, who says, "How much aid in the treatment of the earlier stages of perityphlitis operative interference can give cannot yet be told, as the cases on record are so few."

Aspiration as a Curative Measure.—Noyes mentions seven cases, all of which recovered; but in five a subsequent incision was required later. One was aspirated through the rectum. As a curative measure, aspiration is not to be recommended.

Locating the Abscess by Means of the Aspirator-Needle.—The pain, tenderness of the abdominal muscles, and tympanites may make it impossible to locate even a tumor without narcosis, for which in children chloroform should be used. The tumor may be œdema or infiltration for the most part, including a small amount of pus, in a small focus or a long or flat cavity. Thus, to locate the pus-cavity, a fine aspirator-needle has been used. Opinions differ very widely as to the advisability of this procedure. As a valuable aid to diagnosis, Noyes leaves the needle in, and cuts down upon it as a guide. This is also recommended by Gurdon Buck, W. T. Bull, and Weir. Kraussold advises the eventual use of cautious aspiration. Sands gives an emphatic warning against the use of the exploring-needle at a very early period of the disease, as it might pass through a healthy peritoneal cavity, or through the intestine into the pus-cavity, and, when withdrawn, cause infective diffuse peritonitis. Even at a later stage of the disease this might take place if the puncture were made in front of the tumor. The time-honored procedure of leaving in the needle when pus has been detected, and cutting down upon it as a guide, must be carried out cautiously. When the free peritoneal cavity is encountered over the tumor, the needle should be withdrawn and further incision postponed until adhesions have formed. The wound should be packed with iodoform gauze, and the tear in the peritoneum, from the movements of the needle, sutured. Lange found in an operation, after the usual incision into the free peritoneal cavity over the tumor, that it was covered with omentum. He closed the peritoneal opening, and opened the abscess more laterally where the peritoneum of the abdominal wall was adherent to the tumor. The patient made a good recovery. Smith states that the use of the exploring-needle is liable to serious objections and dangers, and that it is not a useful addition to our means of diagnosis. Ransohoff says, "Place not your faith in exploratory punctures." Morton declares that "the aspirator-needle must never be used, for if it does not find pus we cannot be sure that none is present, whilst its own dangers are not inconsiderable. In these cases it is a poor and especially unsafe diagnostic measure."

Place of Incision.—1. Above and parallel to Poupart's ligament, usually its outer half: Hancock, Parker, the great majority of operations (Noyes). From four to six inches long.

2. Transverse incision above and along the crest of the ilium: Bontecou, Hadden (curvilinear).

3. At the summit of the tumor: Parker, Gibney, Vander Veer (nearer the median line than 1 and 2).

4. Vertical incision over the cæcum is the best, because it affords the easiest access to the presumably diseased parts (Sands, 1888). It is preferable to median laparotomy. The surgeon must know at the outset whether he will perform laparotomy or incision of the abscess.

Lateral Laparotomy.—In speaking of laparotomy for perityphlitis, perityphlitic abscess, or local peri-cæcal purulent peritonitis, it is important to recognize the fact that the general peritoneal cavity is healthy, guarded as yet by limiting adhesions. It is understood also that by the term laparotomy is meant the operation by which the abscess is reached through this healthy peritoneal cavity. It might be termed intra-peritoneal operation for perityphlitic abscess. As a lateral longitudinal incision over the cæcum is the only one that gives ready access to the appendix and its surroundings, and that permits closing of perforations in the appendix and cæcum, or removal of the appendix, it is important to know if this incision can be made, whether a healthy peritoneal cavity is opened or not, and pus evacuated and drained without infection of this healthy peritoneum and consequent fatal peritoneal sepsis. Homans records the first successful case of this kind. A boy eleven years of age had pain in the iliac region for five days; was in bed three days; dulness, tenderness in right iliac fossa; no swelling; pulse 120, temperature 102.4° F. Incision was made half an inch anterior to the spine of the ilium. After opening through the abdominal wall, loops of healthy intestine showed in the wound. On passing the finger below and behind the presenting loops, deeper loops were found agglutinated with recent exudate of adhesive inflammation. Separating these with the fingers, a cavity was opened, from which two ounces of fetid pus welled up. As far as possible the abscess was emptied, and the pus prevented from running in among the coils of intestine. A double rubber drain was introduced into the pus-cavity, and the abdominal incision closed around the projecting end of the tube. There was a free discharge from the tubes for two weeks; temperature varied from 99° to 102.9° F. The patient was out of bed in three weeks after the operation. No exploratory puncture was made before the operation.

It would be dangerous to arrive at general conclusions from a single case. Many unpublished fatal cases of this kind undoubtedly exist, as in my own experience, for instance, in a boy six years old. It is always dangerous to drain an abscess through a healthy peritoneal cavity, as it is beyond the power of surgery to prevent infection along the outside of the drainage-tube. When practicable, and when it has been seen that the lateral incision leads into the healthy peritoneal cavity, it will be safer to close the opening without penetrating into the abscess, and try to reach it at another point where adhesions to the wall have already formed, as has already been stated in the consideration of Lange's case.

Median Laparotomy.—Laparotomy in the linea alba has been resorted to with success by Hoffman, in the case of an adult woman. At the beginning of the second week of the disease the pulse was 128, with high temperature and abdominal tenderness. A median incision was made and the cæcum found adherent to its surroundings. After separating the adhesions, two ounces of fetid pus were found around the discolored cæcum; the appendix was almost buried in pelvic tissue, and was afterwards removed. The pelvis was washed out, no antiseptics being used, however, and a rubber drain inserted through the abdominal wound, which was closed around the tube. The stitches and drain were removed on the tenth day; on the twenty-fourth day the patient was out of bed. She had pain for two years, which ceased upon the removal of the appendix.

As stated above, a lateral incision is always preferred, on account of the easy access to the diseased appendix and its surroundings, and affords a more direct route for drainage than the median laparotomy, which, however, is preferable to lateral incision in cases of diffuse peritonitis.

Operation for Diffuse General Peritonitis.—Laparotomy must be resorted to, and at as early a period as possible, when the peritonitis has no tendency to limitation, but steadily, quickly or slowly, spreads until finally the entire peritoneal cavity is involved. On this question there is no discussion among authors. If the peritonitis can be intercepted on its progressive march from the iliac fossa, while as yet only a portion of the territory is inflamed, so much the better for the patient. We have the choice between lateral and median incision, the former giving better access to the appendix and cæcum for operations on them, the latter affording freer access to the general peritoneal cavity for disinfection and removal of the fluid exudate.

Lateral Laparotomy.—The first successful case on record of lateral laparotomy in a commencing, spreading, and unlimited peritonitis was reported by Sands in 1888. The patient, a boy, forty-eight hours after the onset of the disease had pulse 130, temperature 101.6° F., respiration 32. An incision was made to the parietal peritoneum, which was thickened and opaque. The introduction of the hypodermic needle revealed pus. A free incision into the peritoneal cavity was made, and a little air and an ounce of fetid pus escaped. Both the parietal and the visceral peritoneum on the cæcum and the small intestine were covered with pus and recent exudate. There were no adhesions limiting the spread of the peritonitis, and some coils of small intestine came out through the wound. Through a perforation in the appendix three fæcal concretions escaped. The edges of the opening were trimmed, and the opening was closed by interrupted silk sutures. The abdominal cavity was irrigated with warm water, and then syringed out with half a pint of one to one-thousand corrosive-sublimate solution. The wound was only partially closed, the remainder being packed with iodoform gauze reaching down between the coils of small intestine. No drainage-tube was used. Antiseptic dressing was applied and left on for two days, immediate improvement followed, and an uninterrupted and complete recovery took place.

A most brilliant proof of the success of early laparotomy in perforation of the cæcum has been given by McMurtry. The patient was a young physician, in whom the recurrent attacks of pain, and finally the swelling in the right iliac region, presented the usual symptoms of the onset of perityphlitis. An intestinal hemorrhage of thirty-two ounces marked the beginning of a spreading diffuse peritonitis, which rapidly developed, and the operation was performed after twenty-four hours, at the beginning of collapse. A lateral incision, four inches in length, over the cæcum revealed acute peritonitis on the loops of the surrounding small intestines, which were pushed aside with sponges, and the cæcum lifted out of the wound. On its anterior, external surface were two gangrenous perforations, respectively an inch and five-eighths of an inch in diameter, through the larger of which a free escape of fæcal matter had taken place. The edges of the perforation were trimmed with scissors and united with Lembert sutures of silk; the iliac fossa was washed out with one to forty carbolic-acid solution, and a large rubber drainage-tube was inserted deeply into the fossa. Immediate improvement followed. The drainage-tube was removed in two weeks, with subsequent perfect recovery.

The removal of the perforated appendix, with the permanent closure of its proximal portion, would naturally seem to be an important step in the modern, radical operation for perityphlitis, inasmuch as it prevents continued fæcal extravasation, facilitates the rapid closure of the cavity, and does away with a permanent fæcal fistula. The diseased appendix has been removed in a number of instances in later years, by Sands, Brenner, Hoffman, and others. Morton advises its excision in any case, especially when found inflamed or perforated during the operation for perityphlitis, while we have the opportunity. There is little doubt that its extirpation under these circumstances is desirable; but it is not always easy to accomplish. It is by no means certain that the appendix will present in the wound of incision, or that the cæcum will be sufficiently movable to be brought out through the abdominal wound, so as to permit of easy access and inspection. In most of these cases the appendix is bound down by adhesions at the bottom of the deep abscess-cavity, where unnecessary manipulations should be avoided, for fear of opening into the general peritoneal cavity. Thus, as a rule, we shall have to content ourselves with the evacuation, careful washing out, and drainage of the peri-cæcal collection of pus, without even seeing the diseased appendix. But when the diseased appendix is accessible it should be removed, and its proximal end closed, not by ligation, which has been successfully done, but by invagination, and Lembert sutures if possible.

Median laparotomy has been resorted to in a number of cases of diffuse peritonitis from perforations of the appendix. As a last resort, and the only hope in this desperate condition, the operation is uniformly considered justifiable, although the prospect of success is small. In twelve operations collected from the literature, the mortality was nearly ninety-two per cent. A boy of eighteen, after swallowing cherry-stones, was operated upon on the eighth day. Fetid fæcal pus was found in the peritoneal cavity, more abundantly on the right side. A one to two-thousand sublimate solution was used for the irrigation of the peritoneal cavity. No drain was employed. In cases of this kind operators have usually drained, and probably this procedure was wise.

It is possible that even in this desperate condition more lives might be saved by early operation. From Fitz's statistics it appears that thirty-four per cent. of the patients with perforating appendicitis died during the first five days. To save some of these, operation might have been necessary as early as the third or even the second day. The difficulty of positive diagnosis, however, and the hope of limitation of the peritonitis may prove a barrier in the way of early operation.

I. EXTRAPERITONEAL OPERATIONS FOR ABSCESS.

Operator.	Age.	Sex.	Date of Operation.	Place of Incision.	Contents of Abscess.	Recovery or Death.	Remarks.
Parker	15	F.	14th day.	Over tumor.	Bloody serum and pus.	R.	
Leale	14	M.	. . . . . .	One-third distance from anterior superior spine of the ilium on a line to umbilicus.	Fetid pus.	R.	
Krackowizer	12	M.	11th day.	To transversalis fascia, divided upon director.	Gas and fetid pus.	R.	
Whitall	8	M.	14th "	Along Poupart's ligament.	Fetid pus.	R.	Incision to transversalis fascia. No pus with needle. Operation stopped. Pus escaped third day, fetid.
North	6	F.	20th "	" " "	2 ounces of pus.	R.	Eleven days after abscess, breast-pin escaped from wound.
Buck	12	M.	9th "	Upon trocar as director.	Fetid pus.	R.	Fifth day, sloughing of tissue. Seventh day, phosphatic concretion, size of pea.
Sands	13	M.	21st "	Incision.	Pus.	R.	
Pooley	15	F.	19th "	Over tumor.	Fetid pus.	R.	
Kelsey	11	M.	1 month.	Along Poupart's ligament.	. . . .	R.	Operation abandoned. Incision to fascia. Needles found. No pus. Fifth day, several ounces of fetid pus escaped.
Gibney	4½	M.	. . . . . .	First, aspiration; later, incision.	. . . .	R.	
Sands	11	M.	12th day.	Incision.	. . . .	R.	
Sands	9	M.	13th "	"	. . . .	R.	
Almon Clarke	13	M.	7th "	"	Fetid pus.	R. 15th d.	Incision one inch and a quarter, to transversalis fascia. Aspiration, abscess opened.
Gibney	6	M.	34th "	Over tumor.	1½ pints of pus.	R.

II. LATERAL LAPAROTOMY FOR ABSCESS.

Operator.	Age.	Sex.	Date of Operation.	Operation.	Death or Recovery.	Contents.	Remarks.
Sands . .		Boy.	48 hours.	Vertical incision 1 inch above the outer part of Poupart's ligament, 4 inches long, to 1 inch below level of navel. Opening at base of appendix was closed with stitches through wall, not Lembert's sutures. Irrigation 1:1000 sublimate solution. Drain iodoform gauze.	R.	Air, fetid pus, 3 fæcal stones.	No general peritonitis, but no limiting adhesions.
Homans .	11	M.	5th day.	Incision 1½ inches above and a little posterior to anterior superior spine of ilium. On tender place. Healthy bowel met finger down through adherent intestines. Rubber drain.	R. in 3 weeks.	2 ounces of fetid pus.	No dulness. No swelling. No aspiration. Pulse 120. Temperature 102° F.

III. LATERAL LAPAROTOMY FOR PERITONITIS.

Operator.	Age.	Sex.	Date of Operation.	Operation.	Treatment of Wound.	Death or Recovery.	Remarks.
Sands, 1888	Boy.	M.	48 hours.	Diffuse peritonitis, escape of air, 1 ounce of fetid pus, 3 fæcal concretions.	Washing out and packing with iodoform gauze. No drainage-tube.	R.	
McMurtry, 1888 . . .	Adult.	M.	17th day.	Acute diffuse peritonitis. Gangrenous perforation of cæcum, fæcal extravasation.	Washing out with 1:40 carbolic acid. Drainage.	R.	

IV. MEDIAN LAPAROTOMY FOR PERITONITIS.

Operator.	Age.	Sex.	Date of Operation.	Operation.	Treatment of Wound.	Death or Recovery.	Remarks.
Cushing, 1883.	8	M.	14th day.	Peritonitis.	Washing out.	D.	Next day.
Mikulicz, 1883.	49	M.	5th "	Peritonitis.	Two drains.	D.	On fifth day.
Chaput, 1883 .	. . . .	M.	10th "	Obstructive peritonitis.	Washing out, drainage.	D.	Soon after operation.
Krönlein, 1884.	17	M.	2d "	Appendix removed.	Toilet, abdomen closed, no drain. 1:2000 sublimate on eventrated intestine, no drain.	D.	Two days after operation.
Krönlein, 1885.	18	M.	8th "	No perforation found. Fetid fæcal pus, moist exudate right side.	. . . .	R.	Disease came eight days after eating cherries with stones.
Polaillon, 1884.	19	M.	7th "	Appendix not seen.	Artificial anus.	D.	After ten hours. At autopsy perforation of the appendix.

IV. MEDIAN LAPAROTOMY FOR PERITONITIS—(*Continued*).

OPERATOR.	AGE.	SEX.	DATE OF OPERATION.	OPERATION.	TREATMENT OF WOUND.	DEATH OR RECOVERY.	REMARKS.
Poncet, 1885 .	Adult.	M.	4th day.	Appendix not seen at operation.	Drain.	D.	Same day.
Reignier, 1886.	16	M.	5th "	Perforation of cæcum.	. . . .	D.	After seven hours.
Bryant	49	M.	2d "	Three perforations of appendix.	Washing with 1: 10,000 sublimate.	D.	After twelve hours.
Weir	20	M.	7th " 24 hours after severe pain.	Appendix removed.	Washing out, drainage.	D.	After six hours.
Weir	19	M.	5th day.	Appendix removed.	Eventration, glass drain.	D.	After four hours.

CONGENITAL ABNORMALITIES OF THE INTESTINE.—MALFORMATIONS, INJURIES, AND DISEASES OF THE RECTUM AND ANUS.

By HENRY R. WHARTON, M.D.

CONGENITAL ABNORMALITIES OF THE INTESTINE.

ABNORMALITIES OF THE SMALL INTESTINE.

CONGENITAL malformations of the small intestine occur with much less frequency than those of the rectum and anus. E. Theremin,[1] who has carefully investigated this subject, states that at the Vienna Foundling Hospital only two cases of congenital occlusion of the small intestine were recorded among 111,451 patients, and that at the St. Petersburg Foundling Hospital only nine examples of this malformation were observed in 150,000 children; in the Foundling Hospital of Moscow and Prague no cases were recorded.

Absence of the whole or a large portion of the small intestine is generally met with in ill-developed acephalic monsters.

Congenital occlusion of the small intestine occupies most frequently the duodenum near the point at which the bile-duct and the pancreatic duct open, or at the point where the duodenum becomes jejunum under the transverse mesocolon; malformations of the ileum, also, may exist at any portion of its length, but are most common near the ileo-cæcal valve, or a short distance above it, where the ductus omphalo-mesentericus is given off.

The malformation may consist of a stenosis or atresia of the gut; or the bowel may terminate in a cul-de-sac at the point of obstruction, beyond this point again beginning in a cul-de-sac, and the remaining portion of the intestine may be well developed; or the bowel may have a diverticulum given off which attaches it to the abdominal walls, and this may contain a fistula opening upon some portion of the body; the deformity may also consist of an abnormal shortness of the intestinal canal.

Bodenhamer[2] mentions cases in which both the rectum and the colon were wanting and the small intestine terminated at the umbilicus, in the iliac fossa, or at some portion of the surface of the abdomen.

---

[1] Deutsche Zeitschrift für Chirurgie, 1877, Bd. viii.

[2] Congenital Malformations of the Rectum and Anus, p. 290.

Mr. H. Thomas[1] reports the case of a child who lived four days, in whom, upon post-mortem examination, there was found a congenital absence of the jejunum, the ileum, and a large portion of the colon. In this case there was no trace of any portion of the small intestine except the duodenum, nor of the cæcum, nor of the ascending or transverse colon. The descending colon commenced by a blind extremity, which lay in front of the left kidney and was continued as a sigmoid flexure to terminate in the vagina.

Holmes[2] mentions two cases of congenital occlusion of the small intestine in which the diagnosis was satisfactorily established, and Theremin[3] also reports a number of cases.

A case illustrating this form of congenital malformation of the small intestine is reported by Dr. W. Craig,[4] in which the autopsy in the case of a child who lived seventy-two hours showed an obstruction of the small intestine at the upper fifth of the ileum. The intestine was distended above the point of obstruction, and upon opening the bowel it was found that it ended in a cul-de-sac; further examination of the gut beyond the point of obstruction showed that the intestine began in a cul-de-sac, and the intervening space between these two pouches was occupied by a band of fibrous tissue. The gut below the obstruction contained meconium, and the colon, rectum, and anus were well developed. Mr. W. Thomas[5] reports a somewhat similar case, in which the jejunum terminated in a cul-de-sac at a point thirty-two inches from the pylorus. In these cases it was remarked that if the continuity of the intestinal canal had ever existed it must have been very early in fœtal life. Dr. J. F. Goodhart[6] reports the case of a child who died four days after birth, in whom the intestine beyond the duodenum was contracted to the size of a goose-quill.

Among the congenital malformations of the small intestine may be mentioned that condition known as Meckel's diverticulum, which consists of a cylindrical or flask-shaped appendage attached to the ileum about a metre or more above the ileo-cæcal valve: it is a remnant of the omphalo-mesenteric duct, and it may occur in a variety of forms.[7]

Its presence, according to Birch-Hirschfeld,[8] is to be regarded as due to an arrest of development of the bowel in one of its steps, and the frequency of its occurrence is variously estimated. Osler[9] mentions the presence of twelve cases of this malformation in five hundred and eighty post-mortem examinations; Treves[1] found no case of it in one hundred autopsies.

[8] Pathologische Anatomie, S. 853.

[9] Intestinal Diverticula, Annals of Anatomy and Surgery, vol. iv. No. v., November, 1881.

In the most marked form of this malformation there exists a fissure in the abdominal walls above the umbilicus, through which the ileum opens and through which fæces escape; the bowel below may be narrower than normal. In other cases the ileum may communicate directly with the umbilical opening by means of a patent omphalo-mesenteric duct, the bowel below being well developed: two cases of this nature are reported in Guy's Hospital Report for 1843. In another variety of this malformation the ventral fissure may be closed, and a blind process of the ileum may be attached to the umbilicus by means of a fibrous cord, the remains of the obliterated omphalo-mesenteric duct.

Another form of this defect manifests itself by the presence of a reddish tumor covered by mucous membrane, occupying the position of the umbilicus, which has been variously described by different authors. Holmes speaks of it as a *warty tumor of the umbilicus*, Pearce-Gould terms it *congenital mucous polypus of the umbilicus*, and it has been described by other writers as *adenoma of the umbilicus*. In structure it is similar to the mucous membrane of the intestine.

In this connection should be mentioned those structures, closely allied to congenital diverticula of the intestine, known as *entero-cystomata*, which are closed sacs filled with liquid and exhibiting the same structure as the walls of the bowel. Two forms may be distinguished: (1) cysts due to obstruction and sacculation of portions of an otherwise normally developed intestine; (2) cysts due to some abnormality of development in the fœtus. These latter may be portions of the intestine of a rudimentary twin, and therefore teratoid in character, or may depend on the closure and separation of an anomalous diverticulum such as Meckel's.[2] False diverticula consisting of pouches made up solely of mucous membrane and peritoneum, and varying from the size of a pea to that of a walnut, may be found in some cases throughout the whole course of the small and large intestine. These pouches are often seen at post-mortem examinations, and appear to be productive of no symptoms during life unless they become ulcerated or perforated or become attached to some of the viscera.

Ball[3] mentions a case, reported by Dr. Platt, of a girl aged nine years who died of intestinal obstruction, and in whom at post-mortem examination was found a swelling in the rectum which was probably of this nature.

CONGENITAL MALFORMATIONS OF THE LARGE INTESTINE.

Congenital malformations of the large intestine, like those of the small intestine, are met with much less frequently than those of the rectum and anus, and may involve the colon, the sigmoid flexure, or the cæcum.

---

[1] Anatomy of the Intestinal Canal, 1885.

[2] Ziegler's Pathology, sect. i. p. 279.

[3] Diseases of the Rectum and Anus, p. 399.

Atkin[1] reports the case of a child who died two days after birth, in whom at the autopsy the rectum and colon were found to be rudimentary, smaller than an ordinary quill. In this case attention was called to the fact that the parts had remained in the condition in which they are in the early embryo.

It has also been observed in some of the cases of congenital occlusion of the small intestine, that the colon was rudimentary, and this is markedly the case in those forms of Meckel's diverticulum in which a fæcal fistula exists between the ileum and the fissure above the umbilicus, or where a fæcal fistula exists between the small intestine and some portion of the abdomen.

The recent investigations of Treves[2] have shown that the mobility of the cæcum and colon, owing to the arrangement of their peritoneal attachments, is much greater than was formerly supposed. Lockwood[3] reports a number of cases in which the cæcum and colon occupied anomalous positions, and one in which the cæcum occupied the right hypochondriac region beneath the liver, and in the same case the descending colon was double. The frequent occurrence of the cæcum as part of the contents of a hernial sac has been observed, and Wright[4] reports seven cases of herniotomy in children in which the contents of the sac consisted of this portion of the intestine. Cases of double cæcum have also occasionally been met with.

These various congenital malformations of the small and large intestine are probably largely to be attributed to accidents in development, due to the complicated disposition of the intestinal tract of the embryo, and it is also possible that fœtal peritonitis plays an important part in the production of these deformities, although the fact of its existence cannot be demonstrated in all cases. Theremin is of the opinion that many of the malformations are due to changes in the peritoneum which have taken place early in fœtal life.

Symptoms.—The symptoms resulting from congenital malformation of the large or small intestine are simply those of intestinal obstruction in a more or less marked degree, depending upon the completeness of the obstruction, and all observers are agreed as to the absence of definite symptoms which could enable the surgeon to locate accurately the seat of the lesion. The vomiting of whitish mucus, with obstruction of the bowels, in the case of a new-born child is a symptom which points to an occlusion high up in the small intestine, but if the occlusion exists in the jejunum or the ileum this may be replaced by the vomiting of meconium, and in such a case the symptoms would in no wise differ from those consequent upon an occlusion situated at the lower end of the intestinal canal.

If a fæcal fistula exist, the symptoms of obstruction will not usually be so marked, and its position may be some guide to the surgeon as to the situation of the intestinal malformation.

---

[1] London Lancet, January 31, 1885, p. 203.

[2] Loc. cit.

[3] British Medical Journal, September 23, 1882.

[4] Ibid., March, 1887, p. 506.

Diagnosis.—The diagnosis of the exact location of the malformation of the small or the large intestine cannot in many cases be definitely made out, but in the case of a newly-born child in whom obstruction of the bowels exists, a careful examination should be made of the rectum and anus, to exclude the presence of malformation in this region. If the anus is present, a catheter should be passed and water injected, and if there be no malformation low down in the canal the return stream will bring away meconium: it can then be inferred that the obstruction exists in a higher portion of the intestinal canal. The vomiting of whitish mucus, before mentioned, is also a point in favor of the obstruction being high up in the intestinal canal. Careful palpation and percussion of the belly may disclose the presence of a tumor, or elicit dulness above the seat of obstruction, which may give the surgeon some idea as to the situation of the malformation.

If a fæcal fistula exists at the umbilicus or at another point of the abdomen, the diagnosis of the seat of the malformation is not so difficult; but, upon the whole, I am of the opinion that in most cases an exact diagnosis as to the seat of the malformation is impossible.

Prognosis.—The prognosis of these cases is, unfortunately, a matter of more certainty. Many cases are necessarily fatal from the start,—for instance, those in which the occlusion exists in the duodenum or high up in the jejunum; but, on the other hand, if a fæcal fistula exist not too high up in the intestinal canal, or if the occlusion be not complete, the patient may live for months or years; but complete occlusions are generally fatal within a few days unless relieved by operative treatment.

Treatment.—As regards the treatment of the various forms of malformation of the small or the large intestine, unfortunately the result of such treatment in the cases recorded up to the present time does not present a very encouraging picture; but with the improved manner of wound-treatment due to the antiseptic method now very generally adopted a larger share of successful cases may fairly be looked for.

The deaths after these operations have generally been due to shock or peritonitis, and I feel certain that the former of these causes of death may in many cases be averted by careful attention to the conservation of the bodily heat of the patient both at the time of the operation and afterwards, and that the latter complication may best be guarded against by a rigid adherence to the most exact details of the antiseptic method of operation and wound-treatment.

As before stated, the diagnosis of the exact seat of the lesion is in many cases so obscure, and the symptoms calling for relief are so urgent, that I feel sure that the surgeon, under the circumstances, would consider himself fully justified in undertaking an exploratory operation which should offer even a slight chance of affording relief or of bringing about a cure in a case which, left to itself, must necessarily terminate fatally.

I think a median laparotomy, on the whole, unless some definite symptoms exist which point to the exact seat of the obstruction, should be the operation selected.

If this operation is decided upon, and the abdomen is opened and explored, and the malformation is found to be situated in the duodenum or high up in the jejunum, the case must be abandoned as a hopeless one, unless it be found possible to excise the occluded portion of the bowel and suture together the cut ends of the gut, thus establishing the continuity of the intestinal canal by means of enterorrhaphy; or the operation of intestinal anastomosis, as practised by Senn and Abbe, might be employed with advantage. If the occlusion be found due to a membranous septum, the gut may be incised and the septum exposed and perforated, so as to re-establish the continuity of the canal; the wound in the intestine through which this is done should then be closed by the introduction of Lembert's sutures, and the abdominal wound closed in the usual way.

This, of course, in a child of such tender age would be an operation of difficulty, and one attended by great shock, and would hold out a very slender chance of success; nevertheless, considering the necessarily fatal termination of such cases if left unrelieved, I think it is a procedure which should be adopted. If upon exploration the occlusion be found to exist low down in the jejunum or the ileum, or in the large intestine, the obstruction may be divided or excised, and the ends of the intestine may be brought to the edges of the abdominal wound and secured there by sutures,—in other words, an artificial anus may be established; and, if the patient survives, the continuity of the intestinal canal may be re-established by an operation undertaken at a later period, intestinal anastomosis probably being the best operation to employ. If a fæcal fistula exists, as obtains in some cases of Meckel's diverticulum, and the child does not exhibit symptoms of intestinal obstruction, an operation may be deferred until such symptoms appear, or until the child has attained an age when an operation to establish the continuity of the intestinal canal may be undertaken with more hope of success. If in such a case the symptoms of obstruction are marked or are increasing, the fistulous opening may be carefully dilated or incised, and, if relief be obtained, further interference may be postponed until a later period.

In cases of Meckel's diverticulum with a tumor at the umbilicus where no symptoms of obstruction are present, the base of the tumor should be ligated, and the portion of the tumor in advance of the ligature excised, or destroyed with the actual cautery.

Dr. Holt[1] reports a case of this nature treated successfully by the application of the ligature, and I have recently had under my care such a case in which I applied a ligature, with an equally satisfactory result.

---

[1] New York Medical Record, April 21, 1888, p. 431.

CONGENITAL MALFORMATIONS OF THE RECTUM AND ANUS.

Congenital malformations of the rectum and anus constitute a most interesting class of deformities, not only as regards their production, but also as regards their treatment; and it is essential that all medical men should be familiar with the different varieties of this malformation, as well as with their treatment, for in many cases the saving of life depends upon the promptness with which surgical aid is rendered.

The number of children born with congenital defects of the rectum and anus is small. Zöhrer, of the Vienna Lying-in Hospital, and Collins, of the Dublin Lying-in Hospital, in a joint collection of 66,654 deliveries, found only three cases of imperforate rectum;[1] other observers give the proportion of children born with this defect as about one case in every five thousand births.

PATHOLOGY.

Malformations of the rectum and anus unquestionably result from arrested development of the parts in early fœtal life, and a glance at the development of the intestinal canal will show the method of production of the deformity in some of its various forms.

At its earliest commencement the alimentary canal consists of a simple sac or bag, developed from the innermost layer of the blastoderm, partly within and partly without the body, and in process of development this communication between the two portions of the sac is shut off, and the portion within the abdomen consists of a simple tube—the mesenteron—which terminates at the anterior extremity of the embryo in a blind pouch, while at the posterior extremity a similar pouch is formed.

The cul-de-sac at the anterior extremity of the embryo comes in contact and communicates with an invagination of the epiblast which is called the stomodæum, while a similar depression of the epiblast at the posterior extremity of the embryo, named the proctodæum, forms the anal orifice and communicates with the mesenteron.

The greater portion of malformations of the rectum and anus are due to the latter stages in the process just described being incomplete, or, in other words, to an arrested or irregular development of the proctodæum or mesenteron.

The termination of the rectum in the genito-urinary tract is due, in addition to the arrest of development just mentioned, to a similar arrest of development in the perineal septum which separates the rectum from the genito-urinary tract, both in the early life of the embryo having a common orifice. The failure of development of the perineal septum explains the frequency of cases of imperforate rectum and anus in which there is a communication between the intestinal tube and the genito-urinary tract.

---

[1] Ball, Diseases of the Rectum and Anus.

CLASSIFICATION.

The best classification of malformations of the rectum and anus is that adopted by Bodenhamer,[1] and is as follows:

I. Congenital narrowing of the rectum or anus without complete occlusion.

II. Complete occlusion of the anus by a membranous diaphragm or by well-formed skin.

III. The anus is absent, and the rectum ends in a blind pouch at a point more or less distant from the perineum.

IV. The anus is normal in appearance, but ends in a cul-de-sac, and the rectum ends in a blind pouch at a variable distance above this point.

V. The anus is absent, and the rectum ends by a fistula at any point of the perineum or sacral region.

VI. The anus is absent, and the rectum ends in the vagina, bladder, or urethra.

VII. The anus and rectum are normal, but the ureters, vagina, or uterus open into the rectal cavity.

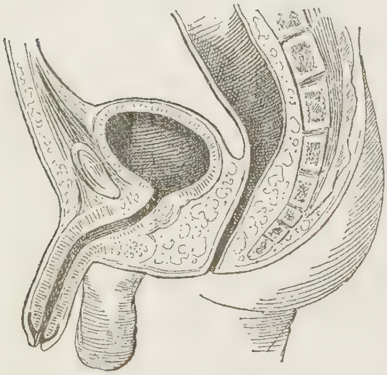
VIII. The rectum is totally absent.

IX. The large intestine is totally absent.

I. CONGENITAL NARROWING OF THE RECTUM OR ANUS WITHOUT COMPLETE OCCLUSION.

Of this variety of malformation few cases are recorded (Fig. 1), but, according to Bodenhamer, it is more common than is generally supposed, and escapes notice if the narrowing is not sufficient to produce marked symptoms of obstruction, and probably in many cases of this nature in which the stenosis is not extreme the efforts of the child in passing the fæces bring about the necessary amount of dilatation. The condition may not be detected for some time, as the stenosis may not be sufficient to prevent the free escape of the semi-fluid fæces of infant life, and it is only as the child becomes older and the fæces become more consistent that accumulation takes place in the rectum and attention is directed to the deformity.

FIG. 1.



Narrowing of the rectum or anus without complete occlusion.

Dr. T. P. Henry[2] reports the case of a child three days old who suffered from a congenital stricture or narrowing of the rectum one and a half inches above the sphincter. In this case the narrowing was so marked that a small probe could with difficulty be passed through it.

---

[1] Treatise upon Congenital Malformations of the Rectum and Anus.

[2] British Medical Journal, May 12, 1888.

In other cases the calibre of the rectum or anus may be diminished by the presence of a perforated membranous septum, or by one or more folds of the mucous membrane, which allow only an imperfect escape of fæcal matter.

Symptoms.—The symptoms of this form of malformation, if well developed, would be those arising from the imperfect escape of fæcal matter,—straining, with the passage of little fæces, pain, and swelling of the abdomen.

Diagnosis.—The diagnosis is made by a careful examination of the rectum, which will disclose the nature of the deformity.

Prognosis.—The prognosis in this variety of rectal malformation is generally favorable.

Treatment.—The treatment of this variety of congenital stenosis is best conducted by gradual dilatation, and the prospect of a permanent cure by this method of treatment is very encouraging. It may be carried out by the daily introduction into the bowel of graduated bougies, or by the introduction of the oiled index finger of the mother or the nurse, which is by far the best of all bougies for this purpose.

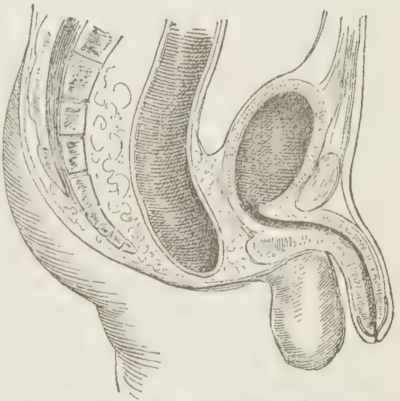
If the occlusion be due to a membranous band, as in a case reported by Cripps,[1] where a band extended from the tip of the coccyx to the perineum or to one or more hypertrophied folds of the mucous membrane, the obstructing band or folds should be divided, and dilatation, either instrumental or digital, should be employed for some time afterwards, to bring about full dilatation of the parts.

II. COMPLETE OCCLUSION OF THE ANUS BY A MEMBRANOUS DIAPHRAGM OR BY WELL-FORMED SKIN.

The closure of the anus in this form of malformation may be by a diaphragm of greater or less thickness, composed of mucous membrane or skin (Fig. 2), and its presence is not incompatible with the development of the sphincter and other portions of the termination of the rectum. It appears to be due to an adhesion or skinning over of the surface of the anus, the rest of the proctodæum being normally formed.

Diagnosis.—The diagnosis of this malformation can be made by observing that the child passes no fæces and that the region of the anus bulges when straining takes place, and fluctuation in the distended rectum may also be detected.

FIG. 2.



Complete occlusion of the anus by a membranous diaphragm or by well-formed skin.

Treatment.—The treatment of this variety of malformation is also simple and satisfactory. It consists in making a crucial incision at the position of the anus, opening the rectal pouch, and evacuating the fæces, and in trimming off the edges of the mucous membrane or skin. The wound should then be dressed with a pad of oiled cotton or lint. The subsequent management of the case consists in keeping the anus well dilated for some time, to prevent cicatricial contraction.

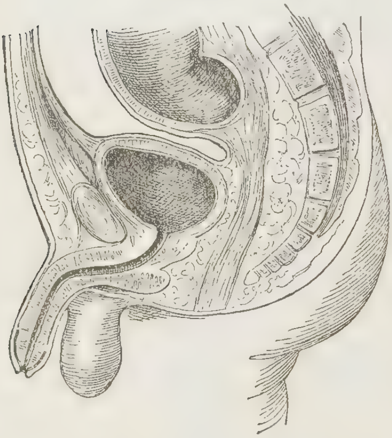
[1] Diseases of the Rectum, p. 25.

III. THE ANUS IS ABSENT, AND THE RECTUM ENDS IN A BLIND POUCH AT A POINT MORE OR LESS DISTANT FROM THE PERINEUM.

In this variety of malformation the rectal pouch may descend well down into the pelvis and may terminate near the skin, or it may end high up in the pelvis and the space between it and the perineum may be filled with cellular tissue, or in other cases a distinct fibrous cord can be traced from the termination of the rectum to the skin. (Fig. 3.)

FIG. 3.



The anus is absent, and the rectum ends in a blind pouch at a point more or less distant from the perineum. (After Mollière.)

Symptoms.—The symptoms of this deformity are very manifest: obstruction of the bowels, pain, and violent straining; the abdomen becomes distended, and fæcal vomiting is apt to occur unless the obstruction is relieved.

Diagnosis.—Inspection shows the absence of the anal orifice, and, if the rectal pouch descends well down into the pelvis, the perineum may bulge upon the straining efforts of the child, and in certain cases fluctuation may be elicited by palpation of the abdomen and perineum. Care should be taken to ascertain whether there is any communication between the rectal cul-de-sac and the genito-urinary tract.

Prognosis.—The prognosis of this form of malformation, as well as of all other forms in which there is complete occlusion, is necessarily very unfavorable, the patients generally perishing within a few days, of intestinal obstruction; although a few cases have been reported in which life has been prolonged for a few weeks, the patient being subject to periodical attacks of fæcal vomiting. Cripps[1] mentions the case of a child two days old who was brought to St. Bartholomew's Hospital with an imperforate rectum. The parents refused to have any operation performed, and took the child away. The case was brought back to the hospital a month later, and it was then observed that the child appeared fairly nourished, but that the belly was much distended; the parents stated that it had fæcal vomiting three times a day. These exceptional cases are so rarely seen that they in no way affect the general prognosis.

---

[1] Loc. cit., p. 28.

In this connection may be mentioned the advisability of operating upon cases of imperforate rectum and anus unless the imperfection is in the immediate neighborhood of the anus: if the latter condition does not obtain, many surgeons are opposed to any interference, which can but leave the child with a contracted anus or an opening in the groin or loin, with its consequent annoyances; but, on the other hand, as will be seen in speaking of the results of the operation, many cases live in comfort for many years. For myself, I feel that it is the duty of the surgeon to operate and save the child from an immediate risk of a most distressing mode of death by intestinal obstruction, even with the chance of leaving the patient with an anus in an abnormal position; and I am of the opinion that the surgeon should urge the performance of the operation in a case of this nature as much as he should tracheotomy or intubation of the larynx in a case of croup suffering from obstructive dyspnœa, or herniotomy in a case of long-standing strangulated hernia; in all these cases the surgical interference relieves the immediate tendency to death and gives the patient a chance for his life.

We are frequently met, on the other hand, by the difficulty of obtaining the consent of the parents, who often express the opinion that they would prefer to have the child die rather than have it live with an anus in an abnormal position. In such cases the surgeon should state fairly and honestly the possible results of the operation, and, if the parents still refuse their consent, he has done his duty and has no further responsibility in the case.

Treatment.—In the treatment of this variety of malformation, and, in fact, of all the forms of imperforate rectum in which complete occlusion exists, the duty of the surgeon is very clear: he should as soon as possible attempt to reach the rectal pouch by perineal incision. I think the earlier this is attempted the better, for delay in operating certainly conduces largely to a fatal result, and I cannot subscribe to the opinion of those who advise delay until the rectum is distended with fæces and gas, which may make the position of the rectal pouch more apparent, but which is not unattended with the risk of rupture of the intestine and exhaustion of the patient. Indeed, it has been shown that by delay the meconium becomes reduced in bulk through the absorption of the fluids.

That rupture of the intestine is a possible result of delay in operating is clearly shown in the history of the case depicted by Fig. 7, and therefore I cannot too strongly urge the importance of early operation in cases of this nature. It is well to remember that the rectum in children descends in the hollow of the sacrum and is close to the bone, and except at its upper portion is uncovered by peritoneum posteriorly: in front its peritoneal investment descends to a much lower level, and its close relation in this aspect to the genito-urinary tract is an additional reason for the selection of the posterior region for exploratory operation.

Puncture with a Trocar and Canula.—Puncture of the rectal pouch with a trocar and canula, introduced through the perineum, was formerly advised, and by its use I have seen the rectum reached and meconium evacuated; but it is generally found necessary to enlarge the wound made by the instrument to secure the free exit of fæcal matter, so that I do not see that its use possesses any advantages over the perineal incision, and I think it has decided disadvantages, for the rectal pouch may be entirely missed by the trocar, and important structures may be injured by its blind introduction.

A number of cases are referred to by Cripps[1] in which examination after death showed that the trocar had failed to enter the rectal pouch,—as happened in a case in my own practice, in which the parents of a child with imperforate rectum of the fourth variety refused the perineal operation, which I first suggested, but agreed to my attempting to reach the bowel by a puncture with a trocar. I failed to reach the rectum, and the child died in a few hours. Upon making a post-mortem examination, I found that the rectum ended in a blind pouch about two inches from the perineum, and that my trocar had passed between the rectal pouch and the sacrum. In this case I think it would have been entirely feasible to open the bowel from the perineum.

At the present time the weight of surgical opinion is decidedly against the operation of puncture with a trocar in cases of imperforate rectum, except where all other forms of operation are refused.

The Perineal Operation.—If the perineal operation be decided upon to reach the rectal pouch,—and I think it is now generally considered the best operation, since if successful it has the advantage of leaving the patient with an anus in the normal position, and often with fair control of the bowels, for the anal sphincter is often well developed in spite of the malformation of the rectum,—the child should be placed in the lithotomy position, and whether an anæsthetic be administered or not will depend upon the judgment of the surgeon; for myself, I prefer not to give an anæsthetic to so young a patient. An incision is now made in the median line of the perineum, and this incision should be carried from behind the root of the scrotum to the coccyx. The tissues should be divided slowly, and any bleeding vessels should be secured as they show themselves. The surgeon should constantly explore the wound with his finger, to find, if possible, the bulging of the rectal pouch, and should remember to make the deepest incisions posteriorly. In a female child some information may be elicited as to the position of the rectum during the operation, by exploring the vagina with the finger or a probe. If the cord-like mass of fibrous tissue in which the rectum sometimes terminates is seen or felt, it may form a valuable guide as to the position of the rectal pouch.

Nearness of the tuberosities of the ischium is a sign of absence of the rectum; and if it is found that the vagina or the bladder fills up the concavity of the sacrum, it is an indication of a high termination of the rectal pouch.

---

[1] Loc. cit., p. 41.

The incision may be carried with safety to a depth of an inch and a half or two inches. When the rectal pouch is reached, it should be incised, and, when the meconium has escaped, the wound in the rectum should be sufficiently enlarged, and then, if possible, its edges should be brought down and sutured to the skin of the perineal wound, care being taken, by passing the sutures deeply and by introducing a drainage-tube, to leave no pocket around the bowel for the accumulation of discharges.

The suturing of the edges of the bowel to the skin may be found impossible in certain cases if the rectum terminates high up in the pelvis, but if it can be accomplished it is a most important procedure, and one which diminishes largely the amount of contraction in the newly-formed anus. If it is found impossible to bring down the edges of the rectal wound to the skin, a large flexible catheter or a metallic tube may be introduced and held in place by tapes; but it is almost impossible to keep it in position, as it is apt to be displaced by the straining efforts of the child.

A very valuable modification of this operation has been suggested and practised by Verneuil,[1] and has been very favorably commented upon by those who have made use of it,—namely, excision of the coccyx in the early part of the operation, which greatly facilitates the search for the gut, and, in case it is found, enables the surgeon more readily to attach the edges of the rectal pouch to the skin.

Vincent[2] has suggested the following procedure in cases of this nature, which consists in making an incision five centimetres in length on the natural site of the anus, its posterior extremity passing the tip of the coccyx by one centimetre. The rectal pouch is found and mobilized by the use of the finger and director, and the anterior face of the coccyx and sacrum is also exposed. By this plan no organ can be wounded, and the rectal pouch, which is recognized by its dark color, is more surely reached. When it is found and its adhesions are ruptured by the finger, it is brought down to the surface of the skin by gentle traction without being opened. The next step is to determine the level of insertion of the rectal pouch. If the bottom of the pouch comes to the skin without any traction, all is well; but if, on the contrary, it has to be dragged down to this level, the perineal incision must be prolonged beyond the coccyx and along the side of the sacrum until the rectal pouch rests easily on the level of the incision and remains there without traction. Two semilunar flaps of skin are then removed, causing an ovoid loss of substance with its long axis antero-posterior, with the object of preventing subsequent retraction of the anal orifice. The internal sphincter must be relied upon to prevent incontinence of fæces, and in none of

---

[2] Annual of the Medical Sciences, 1888, vol ii.

Vincent's cases has this occurred. The sutures are placed in two consecutive planes. If the rectal pouch is intact, its lowest part should pass two or three centimetres beyond the cutaneous wound, and should be fixed to the borders of the wound by catgut sutures. The pouch is then opened, and after the meconium has escaped, a constant flow of antiseptic fluid being maintained, the free edges are pared off, and the gut is attached to the skin of the margin of the wound by a row of fine silk sutures. If the pouch has been torn during the other steps of the operation, the first row of sutures is placed so that the knots shall be inside of the new anus. The second row is passed as in the previous case, and in this manner all possibility of infiltration of the peri-rectal cellular tissue is obviated. This procedure overcomes the tendency on the part of the rectum to ascend when the sutures relax, the mucous border remains, and the ablation of the skin secures the permanence of the artificial anus.

The dressing of the wound should consist in dusting the parts with iodoform, and in keeping applied a pad of cotton moistened with some antiseptic solution, to collect the discharges; this pad should be changed as often as it becomes soiled, and the wound should also be kept clean by the use of a weak solution of bichloride of mercury or carbolic acid.

If the surgeon has carried his dissection up into the pelvis as far as he considers it safe, an inch and a half or two inches, and has failed to reach the rectal pouch, he should now consider the advisability of abandoning the attempt to reach the gut through the perineum, and should endeavor to open the large intestine either in the left groin,—Littre's operation,—or in the left loin behind the peritoneum,—Amussat's operation,—or in the right groin,—Huguier's operation.

The objections to the performance of Amussat's operation in children are the difficulty of finding the descending colon, which is much more movable than in the adult by reason of the length of its peritoneal attachment, and the fact that the relatively large size of the infant's kidney limits the space in which the operation is performed. Huguier's suggestion to make the incision in the right groin to open the sigmoid flexure of the colon, grounded upon the observation that this portion of the intestine is frequently in young children curled over so as to assume this position, has not generally been accepted. He also points out the fact that if the sigmoid flexure is not met in this position, the cæcum or some other part of the large intestine may be reached and opened. But experience shows that the sigmoid flexure occupies much more frequently the left side, for Bourcart,[1] in one hundred and fifty post-mortem examinations made to elucidate this point, found the sigmoid flexure in its normal position in one hundred and seventeen cases: so that I think it is clearly shown that the opening in the right groin is not to be recommended. I think that all authorities are now agreed that Littre's operation, or laparo-colotomy in the left groin, which opens the bowel near its natural termination, is the best procedure to adopt when it is found impossible to perform the perineal operation.

---

[1] Holmes, Surgical Treatment of Children's Diseases, p. 179.

If the surgeon decides upon this operation, he should make an incision from one and a half to two inches in length, half an inch above and parallel with Poupart's ligament, beginning at a point opposite the junction of the middle with the outer third of this structure. Or, as suggested by Ball, an incision of sufficient length following the line of the linea semilunaris, stopping just short of Poupart's ligament, may be substituted for the former incision. The skin and muscular layers being cut through, the fascia transversalis and peritoneum may be pinched up together, and a small opening made in them, through which a director should be passed, and the two can be then divided with one incision. At this step of the operation the edges of the wound may be everted, and the peritoneum secured to the edges of skin.

It is sometimes difficult for the surgeon to determine whether the bowel presenting in the wound is small or large intestine; this can be ascertained by gently drawing outward the coil: if it be the small intestine it can be drawn out with ease, and the mesentery will show that it is not the portion of the bowel which is sought for, whereupon it can be replaced. On the other hand, the large intestine cannot be so readily drawn out, and its mesocolon, if it have one, will be found attached to the left side.

When the surgeon has satisfied himself that the presenting gut is large intestine, he should before opening it secure the bowel to the edges of the wound by several sutures of fine silk or catgut. In making these sutures a curved needle should be passed through the skin and parietal peritoneum near the edge of the wound and should then transfix a portion of the bowel, after which the needle should again be passed through the peritoneum and skin: several sutures should be applied on each side of the incision. The gut may now be incised to a sufficient extent, and the meconium allowed to escape, care being taken to prevent its entrance into the peritoneal cavity.

Before dressing the wound the surgeon may explore the gut with his finger or with a flexible catheter, to locate the termination of the rectal pouch with reference to its proximity to the perineum, and if it is found that it approaches the perineum he can at this time deepen the perineal incision on a guide introduced through the artificial anus just made, or he can postpone to a later period the attempt to form an anus at its normal position.

Attempts to establish an anus in the perineal region immediately after the performance of colotomy in these cases are attended with so much danger, and have been so unsuccessful, that I think the judicious surgeon will rest contented with the relief which has been afforded by colotomy. Mr. Owen[1] attempted this procedure in two cases three months after colotomy, with a fatal result in both. Dr. Byrd[1] has reported a successful case; and Krönlein,[2] in a case of imperforate rectum, in which the anus terminated in a narrow pouch two and a half centimetres long, succeeded in estabblishing the continuity of the gut seven months after the performance of colotomy. If, however, the patient has attained some age, and an examination through the artificial anus in the left groin shows that the rectal pouch terminates well down in the pelvis, a director or rubber catheter may be introduced through the colotomy-wound and made to enter the rectal pouch and project at the anus if it be present, or at some point of the perineum. This may then be cut down upon, and the gut may be opened and sutured to the skin if possible. Or the method of Demarquay may be adopted, which consists in passing a thread carrying a leaden ball through the artificial anus and out at the anus if it be present, or through the perineum, so as gradually to draw the gut downward.

---

[1] Surgical Diseases of Children, p. 309.

McLeod[3] has suggested that after the colon has been exposed by laparotomy the perineal incision should be continued so as to open the peritoneal cavity, and that instead of bringing the bowel out at the abdominal wound it should be drawn down and opened and fastened to the edges of the perineal wound.

The operation should be done with full antiseptic precautions, and the wound in the groin dusted with iodoform and dressed with a pad of antiseptic cotton, which should be changed as often as it becomes soiled.

If, for any reason, the surgeon should prefer making the attempt to open the bowel in the loin, the best guide to the position of the colon is a line half an inch posterior to a point midway between the two superior processes of the ileum: the disadvantages of Amussat's operation have been alluded to. If the surgeon fails to find the large intestine, and the distended small intestine shows itself in the wound, it is better to open this and stitch it to the wound rather than to abandon the case and allow the child to perish by intestinal obstruction.

As regards the results obtained by the various operations for the relief of the symptoms due to imperforate rectum, there is no doubt that, in point of safety and as a matter of comfort to the patient, the weight of evidence is largely in favor of the perineal operation.

Cripps[4] has collected one hundred cases of the various operations for the relief of imperforate rectum: his table, although exhibiting a high rate of mortality (fifty per cent.), shows that the largest number of recoveries followed the perineal operation, and that next in number were those cases in which the colon was opened in the groin.

The number of well-attested cases collected by Cripps, Holmes, and other surgeons, in which children with an imperforate rectum have been operated upon successfully and have lived for years afterwards in comfort, shows that the operation for the establishment of an artificial anus, either in the perineum or in the groin, does not relegate the patient, if he survives, to a life of misery, and cannot, I think, fail to convince even the most conservative surgeon of the humanity and utility of operative interference in such cases.

[2] Berlin. Klin. Wochenschr., 1879, Nos. 34 and 35.

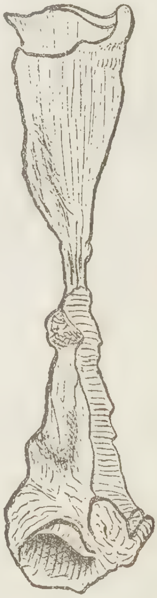
[3] British Medical Journal, 1880, vol. ii. p. 657.

[4] Loc. cit., p. 38.

IV. THE ANUS IS NORMAL IN APPEARANCE, BUT ENDS IN A CUL-DE-SAC, AND THE RECTUM ENDS IN A BLIND POUCH AT A VARIABLE DISTANCE ABOVE THIS POINT.

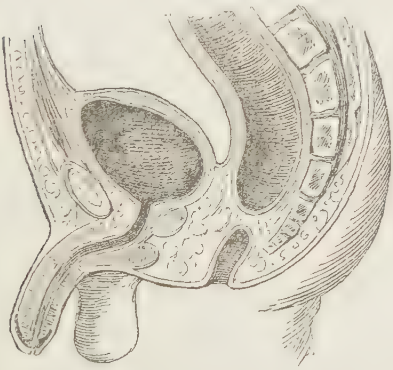
In this form of malformation the anus and the rectum may be separated by a membranous partition of greater or less thickness (Fig. 4), or a portion of the bowel may be impervious (Fig. 5), or there may be multiple obstructions, or the anal portion may communicate with the vagina in the female (Fig. 6) and the rectum end in a cul-de-sac, as in the celebrated case of Amussat, in which the anus was well formed and communicated with the vagina while the rectum ended in a cul-de-sac (Fig. 5): the cases also in which the anus ended in a sinus passing in front of the prostate gland and the rectum terminated in a closed pouch should be mentioned in this connection. The case of Amussat's is of interest, as it was the one in which he first brought down the rectum and stitched it to the skin, introducing a procedure which is now very generally adopted.

Fig. 5.



A portion of the rectum which terminated in an impervious cord, the anus being normal, removed from a child who died two days after birth.

Fig. 4.

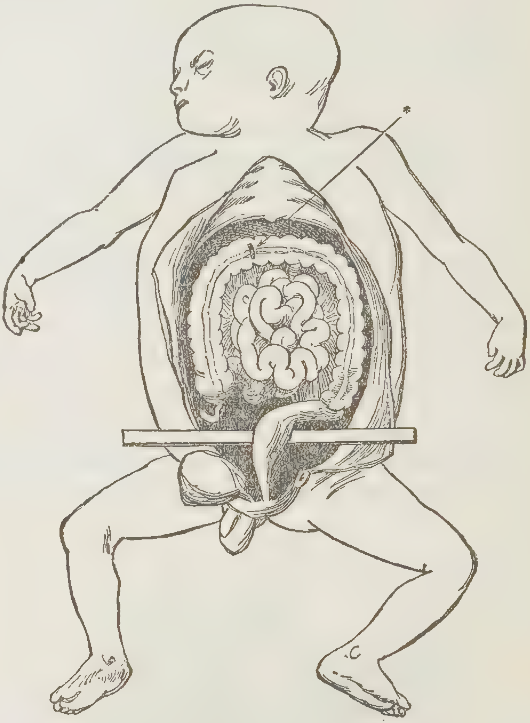


The anus is normal in appearance, but ends in a cul-de-sac, and the rectum ends in a blind pouch at a variable distance above this point. (After Mollière.)

The first variety of this malformation, where the anus is normal but is separated from the rectum by a membranous partition of greater or less thickness, is not an uncommon form. I have myself seen a number of such cases, and through the kindness of Dr. H. F. Formad I had recently an opportunity to examine a child presenting this malformation who died three days after birth, apparently from peritonitis resulting from a rupture of the transverse colon (Fig. 7).

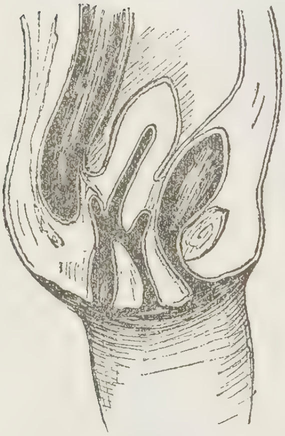
Symptoms.—The symptoms presented in cases of this nature are in no wise different from those presented in any case of complete occlusion.

FIG. 7.



Dissection of a child in whom the fourth variety of this malformation existed, who died of peritonitis resulting from rupture of the transverse colon three days after birth. * Point at which the rupture occurred.

FIG. 6.



Rectum ending in a cul-de-sac, anal portion opening into the vagina. (After Amussat.)

Diagnosis.—The diagnosis of the nature of the occlusion in cases of this variety of malformation is not often made early, as inspection of the part shows the anus to be normal, and it is only when the nurse or mother notices that the child passes no fæcal matter and that it suffers pain, and when the belly becomes swollen or vomiting begins, that the surgeon's attention is directed to the case. An examination of the anus with the finger or a probe will then reveal the nature of the trouble.

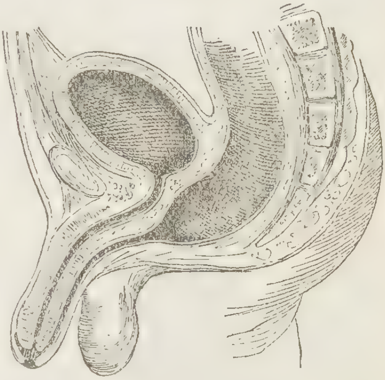
Prognosis.—From the fact that the nature of the malformation is not often, in these cases, diagnosed until grave symptoms have made their appearance, the prognosis is usually most unfavorable.

Treatment.—In this variety of malformation an attempt should first be made to reach the rectal pouch by an incision through the anus back towards the coccyx, and if the gut be found it should be brought down and sutured to the edges of the anal wound. This is a much safer procedure than puncture through the anus, which the surgeon might feel tempted to employ if the partition between the two cavities did not seem to be very thick. If a careful and safe dissection in the perineal region fails to reveal the presence of the rectal pouch, the surgeon should abandon this operation and should attempt to reach the gut by an incision in the left groin.

V. THE ANUS IS ABSENT, AND THE RECTUM ENDS BY A FISTULA AT ANY POINT OF THE PERINEUM OR SACRAL REGION.

The rectum in this variety of malformation may open, as stated, at some portion of the perineum or sacral region, or it may terminate in a narrow channel under the raphé of the perineum and open at the prepuce (Fig. 8) or at the symphysis pubis, or may terminate in several fistulæ at different points.

Fig. 8.



The anus is absent, and the rectum terminates in a narrow canal opening at the prepuce. (After Mollière.)

Diagnosis.—The diagnosis of this variety of malformation is generally not difficult, as the absence of the anus and the presence of a fistula through which fæcal matter is discharged will clearly point to the nature of the trouble, and a probe introduced into the fistula will often give the surgeon some information as to the position of the rectal pouch.

Prognosis.—In these cases the prognosis is more favorable than in those in which complete occlusion exists, for such cases may have satisfactory evacuations through the fistula for some time, and may even live for months or years without suffering any inconvenience from the deformity.

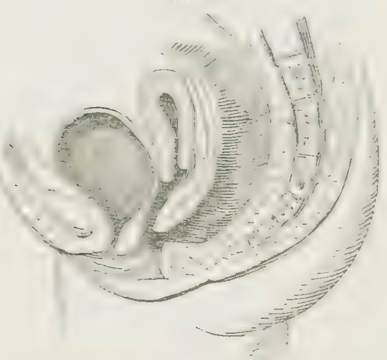
Treatment.—If the passage of fæces through the fistula is not sufficiently free and the child begins to show evidence of discomfort, the fistula should first be dilated or carefully increased in size by incision, and if this gives relief from the symptoms presented it should be dilated daily, and no further operation should be attempted as long as the child remains in comfort, or until it has attained an age when a more radical operation may be undertaken with a fair prospect of success. If this does not give relief, or the child has attained a sufficient age, the fistula may be explored with a probe or director, and the position of the rectum ascertained if possible. Having ascertained this, a perineal opening should be made to reach the rectum, and, if this can be accomplished, the bowel should be opened and its edges brought down and sutured to the skin. An attempt may be made to close the fistulous tract at this time (or it may be postponed until a later occasion) by the use of the actual cautery or by laying it open and allowing it to heal by granulation if it be subcutaneous.

VI. THE ANUS IS ABSENT, AND THE RECTUM ENDS IN THE VAGINA, BLADDER, OR URETHRA.

These varieties of malformation, according to the point of termination of the rectum, are classified as *atresia ani vaginalis, atresia ani vesicalis,* and [illegible]. Their frequency is remarkable, for in Leichtenstern's statistics[1] forty per cent. of all malformations were of this nature, and Bodenhamer's statistics also show their great preponderance as compared with other forms. This marked tendency of the rectum to terminate in the genito-urinary tract is remarkable when we consider the very definite separation which exists between the rectum and the anterior perineum in the adult: it is attributed by Ball to the method of development of the proctodæum, or a tendency to reversion to the cloacal type of the birds and lower mammals.

Atresia Ani Vaginalis.—In that form of malformation in which the rectum terminates in the posterior wall of the vagina, which is the most common form, there may be a small opening allowing an insufficient escape of fæcal matter, or there may be a large aperture permitting of a free escape of the contents of the bowel (Fig. 9). The opening may be situated immediately within the fourchette at the entrance of the vagina, or may be located high up in the canal. The symptoms of this malformation depend largely upon the size of the rectal opening.

Fig. 9.



The anus is absent, and the rectum terminates in the posterior wall of the vagina.

Diagnosis.—The diagnosis of the case can easily be made by noting that the anus is absent, and that there is an escape of fæcal matter from the vagina.

Prognosis.—The prognosis in this variety of malformation is favorable, and, if the opening into the vagina is sufficiently large, the child may experience no discomfort. Numerous cases are on record in which patients suffering from this deformity have grown up, have married, and have borne children.

Treatment.—If, as often happens, the patient suffers no inconvenience from this malformation, any operation looking towards its cure may be postponed until the patient has attained some age, when the greater development of the parts will conduce to a favorable result. With this end in view, the surgeon may, in cases in which the opening is not sufficiently free, first attempt to overcome this complication by dilatation or enlargement by a careful incision of the fistulous opening.

Should a more radical operation be decided upon, the one which I have seen followed by the best results is performed in the following manner. A director is first introduced into the vaginal opening, and is pushed backward, its point being made to project as much as possible near the normal position of the anus; this is then cut down upon from the perineum, and when the rectum is exposed it is incised. The rectal wound being then enlarged to a sufficient extent, the gut is dissected loose, and the edges are brought down and secured to the skin by sutures; by this dissection of the rectum and bringing down of its edges the opening into the vagina is often obliterated if it be a low one. Care should be taken to secure close approximation of the gut to the skin, and to provide for drainage by the introduction of a drainage-tube. The after-treatment of the case consists in keeping the wound dressed with a pad of cotton saturated with some antiseptic solution, and in seeing that the artificial anus is kept properly dilated so as to prevent contraction.

---

[1] Ziemssen's Cyclopædia, vol. vii. p. 485.

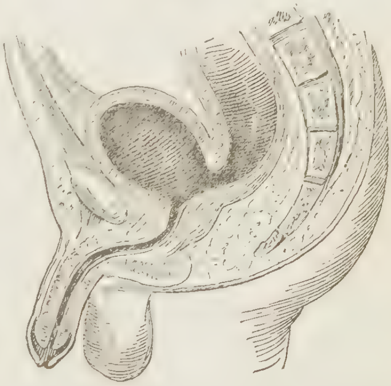
If the opening into the vagina is situated high up, and has not been obliterated by the operation, at a later period, when the parts have increased in size, an operation may be undertaken to close the recto-vaginal fistula, with a good chance of success.

An operation devised by Rizzoli[1] for the relief of this malformation, which retains the outlet that nature has provided, is performed as follows. An incision is carried from the lower margin of the vaginal anus backward through the perineum towards the coccyx, care being taken not to open the intestine. The termination of the rectum, with its vaginal orifice, is now carefully dissected out, and the abnormal anus is transplanted to its natural situation and secured in that position by a few sutures, after which the perineal and vaginal wounds are brought together by deep sutures.

It has been suggested that an incision be made backward from the vaginal opening, including the tissues of the perineum, and opening the rectum, and that a tube be then introduced and held in place by sutures or tapes, the wound thus made being allowed to heal by granulation; but I think either of the operations recommended above will be found more satisfactory.

The operations for the relief of this variety of rectal malformation are, I think, the most satisfactory in their results of all those that have been devised for the cure of congenital malformations of the rectum.

FIG. 10.



The anus is absent, and the rectum terminates in the bladder. (After Mollière.)

ATRESIA ANI VESICALIS.—In that form of malformation which is known as atresia ani vesicalis the rectum communicates with the bladder, either by a narrow orifice near the base of the organ, or by an opening near its fundus (Fig. 10).

Symptoms.—The most marked symptom of this form of malformation is the passage of fæcal matter with the urine, accompanied generally, in consequence of the insufficient passage of fæcal matter, with pain and straining, and swelling of the belly.

---

[1] Gross, System of Surgery, vol. ii. p. 605.

Diagnosis.—This is generally made without much difficulty, as there is absence of the anus, and symptoms of occlusion of the rectum generally exist to a greater or less degree, and a small quantity of fæces intimately mixed with the urine escapes during urination and not at other times, showing that the opening is into the bladder and not into the urethra.

Prognosis.—In this variety of malformation the prognosis is not favorable, from the fact that the bladder in the infant is situated so high up in the pelvis that it is really an abdominal organ, and hence there must be a high termination of the rectal pouch.

Treatment.—In the treatment of this very serious form of malformation several difficult operations have been recommended and practised. Martin[1] suggests the introduction of a staff through the urethra into the bladder, and an incision of the neck of the bladder as in lithotomy, which should continue into the rectum. This operation relieves the immediate symptoms of obstruction, but leaves the patient with a urinary and fæcal fistula, which would have a great tendency to contract and would be followed by a return of the symptoms of obstruction.

I had the opportunity, a few years ago, of assisting Prof. Ashhurst in performing this operation upon a child a few days old who had been brought to the University Hospital suffering from symptoms of obstruction due to this malformation. In this case the operation was accomplished without much difficulty, and the result was most satisfactory as regarded the comfort of the child while under our observation for a period of two or three weeks; but, unfortunately, the case after this time passed out of observation, and I was unable to ascertain the ultimate result of the procedure.

Ball[2] suggests a laparo-colotomy, and, when the colon has been found, its complete division, with closure of the lower portion and the bringing out of the upper end of the colon at the wound and securing it in that position to establish an artificial anus. This latter operation, although attended with greater immediate risk than the one before mentioned, has the advantage of leaving the patient with control over his urinary secretion.

Atresia Ani Urethralis.—In that form of malformation known as atresia ani urethralis the rectum communicates with some portion of the urethra, allowing the escape of a small amount of fæcal matter, which passes more or less in the intervals between urination (Fig. 11).

Diagnosis.—This condition may be suspected from the fact that the fæces escape during the intervals between urination, and, although the urine may contain fæcal matter, it is not intimately mixed with it, as is the case when the rectum communicates directly with the bladder; also it passes during the early part of urination, the urine at the latter part of the act being perfectly clear.

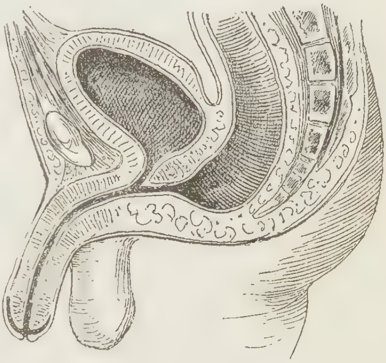
---

[1] Dictionnaire des Sciences médicales, tome xxiv.

[2] Loc. cit., p. 41.

Prognosis.—In cases of this nature the prognosis is, as a rule, unfavorable, as the rectal opening into the urethra is usually so small that the fæces cannot escape in sufficient quantity, and symptoms of intestinal obstruction are rapidly developed. But that it is possible for a child suffering from this malformation to live for some time in comfort is shown by a case recently reported by Mr. Page,[1] in which a man fifty-four years of age, with an imperforate anus, who passed his fæces through a fistulous opening in the urethra in front of the scrotum, was admitted to the hospital with symptoms of obstruction of the bowels, dependent upon occlusion of this opening by inspissated fæces. The opening was enlarged, and, his symptoms being relieved, he left the hospital, refusing to submit to further operative treatment.

Fig. 11.



The anus is absent, and the rectum terminates in the urethra.

In this case the patient was born with an imperforate anus and a communication between the rectum and the urethra, and, an attempt to make an anal opening having proved unsuccessful, he passed his fæces by the urethra until he was ten years of age, at which time the urethra became occluded by inspissated fæces, and an opening was then made in front of the scrotum, through which he continued to have satisfactory evacuations until he was admitted to the hospital.

Treatment.—The treatment of this form of malformation consists in finding the rectum by means of a perineal incision; and, as the gut is low down, this is generally accomplished without difficulty. The details of the operation are similar to those before mentioned, and need not be repeated. F. J. Sheppard[2] reports a case of this nature, in which he reached the rectum by perineal incision, and brought it down and sutured it to the edges of the wound, with a satisfactory result. Dr. Cabot[3] reports a similar case, in a child five weeks of age, in which he operated, with an equally satisfactory result.

In this connection it is interesting to note a case mentioned by Ball, in which a diverticulum from the rectum passed forward and was intimately associated with the urethra but did not communicate with it, which was successfully operated upon in after-life.

[3] Medical News, November 10, 1888, p. 526.

VII. THE ANUS AND RECTUM ARE NORMAL, BUT THE URETERS, VAGINA, OR UTERUS OPEN INTO THE RECTAL CAVITY.

This is a rare form of malformation, but it is not one that is incompatible with life. Bodenhamer has collected a number of cases in which the ureters opened into the rectum, the bladder being absent.

As this is a malformation in which occlusion of the bowels does not exist, and as life is not endangered by its presence, no immediate operation is called for.

In that form in which the vagina or uterus opens into the rectum, when the child has attained some age and the parts are well developed, an operation to close the fistula and replace the organs in their normal position may be attempted with a fair prospect of success. In cases in which the ureters open into the rectum no operative interference could be of any avail.

VIII. THE RECTUM IS TOTALLY ABSENT.

This form of rectal malformation differs from the third variety of malformation only in the amount of the rectum which is wanting, and its existence may be suspected in those cases in which an exploration of the pelvis by perineal incision fails to reveal the presence of the rectal pouch.

The treatment of this condition is by laparo-colotomy, preferably in the left groin, and the formation of an artificial anus.

IX. THE LARGE INTESTINE IS TOTALLY ABSENT.

When this condition exists it is often associated with a fæcal fistula at the umbilicus or some other portion of the body, and, aside from the securing of free exit of fæces from this fistula, either by dilatation or by careful incision, is, unfortunately, beyond the reach of surgical aid.

Cases of this nature have already been described under the head of abnormalities of the large intestine.

DISEASES OF THE ANUS.

PRURITUS ANI.

Pruritus ani is an affection which is occasionally seen in childhood, and is characterized by a painful itching of the anal region, which causes the child constantly to scratch the part, the skin in the vicinity of the anus becoming thickened, eczematous, and moist from exudation as a result of the irritation thus produced.

Pruritus ani may result from various causes,—for instance, from eczema of the anus or from the presence of oxyuris vermicularis in the rectum, from pediculi or scabies, or from the presence of a vegetable parasite, as is the case when the itching is due to the affection known as eczema marginatum.

Dr. Hare[1] has recently reported a case of that rare affection *aspergillus* of the anus, occurring in a boy four years of age. In certain other cases, in which its presence is not to be attributed to any of the above-named causes, it can be traced to improper diet or chronic constipation. The latter condition is not uncommon in infants, and is due, as was pointed out by Jacobi, to a number of flexures in the lower part of the colon, in which fæces are arrested, giving rise to an obstinate form of constipation.

Treatment.—Where the condition can be traced to the presence of eczema, the parts should be frequently bathed with hot water and washed carefully with green soap, and, if this does not effect a cure, one of the following lotions may be used:

℞ Acidi carbolici, ♏xxx;
Liq. calcis, f℥vi.
Misce.

℞ Acidi carbolici, fʒi;
Glycerini, f℥i;
Aquæ, q. s. ad f℥vi.
Misce.

Or the following ointment may be employed:

℞ Ungt. picis, ʒi;
Ungt. zinci ox., ʒiii;
Ungt. aq. rosæ, ʒiv.
Misce.

When the itching can be traced to the presence of parasites, either animal or vegetable, the use of some of the antiparasitic lotions or ointments appropriate for the individual case will rapidly relieve the condition. In cases in which the affection is dependent upon errors in diet, a change of diet will often be followed by a satisfactory result. Where the trouble arises from chronic constipation, the diet should be changed, and enemata or suppositories of glycerin should be employed in preference to purgative medicines.

SYPHILITIC AFFECTIONS OF THE ANUS.

Mucous Patches, Moist Papules, Condylomata.—Mucous patches and moist papules are affections which occur with comparative frequency in the region of the anus as the result of congenital syphilis. Allingham speaks of numerous tracks or fissures of the mucous membrane of the anus in children suffering from hereditary syphilis. Condylomatous growths may appear upon these syphilitic lesions, which are acuminated and spring from previously-existing papules or mucous patches, and are accompanied by a very fetid discharge of a characteristic odor: these growths are to be distinguished from the simple form of vegetations which frequently occur in this region in children and which are in no way dependent upon the presence of inherited syphilis.

---

[1] University Medical Magazine, June, 1889, p. 525.

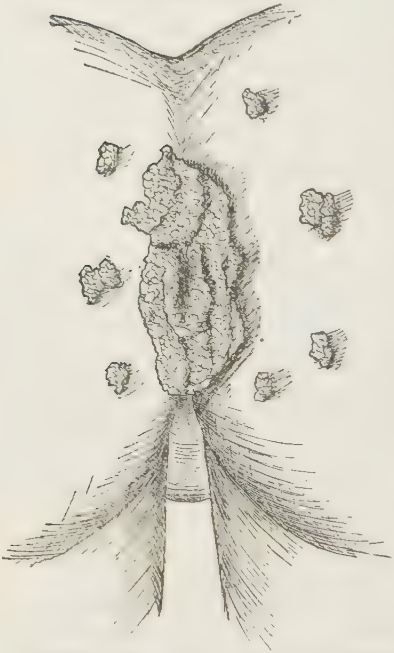
The appearance of these lesions is so characteristic that the diagnosis is not difficult.

Treatment.—The treatment of these syphilitic lesions of the anus should be both constitutional and local. The constitutional effects of mercury can best be obtained in young children by the use of a binder spread with mercurial ointment applied around the abdomen. The local treatment of the anal lesions should consist in the application to them of the solid stick of nitrate of silver, or of the acid nitrate of mercury, or in dusting them with a powder composed of equal parts of calomel and oxide of zinc. Under this treatment they will generally rapidly disappear.

VEGETATIONS OR WARTS OF THE ANUS.

Vegetations of the anus are often seen in children, and the masses may attain great size (Fig. 12). They are papillary overgrowths similar in structure to warts situated in other parts of the body, and are covered with a squamous epithelium. From their situation, they are apt to become moist, and as a result of this condition there is often present a certain amount of offensive discharge.

FIG. 12.



Vegetations around the anus: from a patient in the Children's Hospital.

Treatment.—In the treatment of these growths, if the parts can be kept perfectly dry a cure may rapidly result, and, with this end in view, if the growths are not very large, dusting the parts with lycopodium and powdered oxide of zinc will often be followed by their rapid removal.

They may also be touched with the solid stick of nitrate of silver or with a saturated solution of chromic acid. If the masses are large they may be destroyed by the application of the actual cautery, or they may be trimmed away with scissors: the objection to the latter means of removing them is the profuse hemorrhage which may result, but this can generally be controlled by the application of a firm compress to the bleeding surface.

FISTULA IN ANO.

Fistula in ano is an affection in which there is an abnormal communication between the mucous surface of the rectum or anus and the skin in its immediate neighborhood, and when the above conditions exist it constitutes what is known as a complete fistula. When the fistulous tract has only one aperture, either mucous or cutaneous, it is termed an incomplete fistula.

This affection is certainly very rare in infants and children, but does occur with sufficient frequency in this class of patients to render its diagnosis and treatment most important. Allingham mentions the fact of its occurrence in children of a very tender age; and I have seen a number of such cases at the Children's Hospital and call to mind a case of complete fistula in a child a few months old.

The condition may result from wounds involving the anus or rectum, from perforating ulceration of the mucous membrane of the rectum, and probably with greater frequency from ischio-rectal abscess opening into the rectum or through the skin in the vicinity of the anus. The causes of ischio-rectal abscess are in many cases difficult to make out, but I think it may be due to a phlebitis or periphlebitis of the hemorrhoidal veins resulting in suppuration.

Diagnosis.—The diagnosis of this affection is generally rendered sufficiently simple by the introduction of the finger into the rectum and a probe into the external opening, when by a little careful manipulation the latter may be made to enter the bowel if the fistula be a complete one. In incomplete fistulæ which have an opening upon the skin, or in those cases in which the opening is only into the rectum, the diagnosis is not so clearly made out. In the former class of cases, if the finger be introduced into the rectum and a probe be passed into the external opening, it can be felt at some point to come near the wall of the bowel; and in the latter class, if the surgeon palpates the tissues surrounding the anus carefully with the finger, he will often feel an indurated mass of tissue which indicates the position of the internal fistula. The finger introduced into the rectum may also feel the orifice of the internal opening, and the discharge of pus with the stool points to the existence of this affection.

In this connection it should be remembered that in certain cases of disease of the bones of the spine, of the sacrum, or of the pelvis, the purulent matter may find its way to the surface through the connective tissue about the rectum and perforate the skin in the neighborhood of the anus, or it may open into the rectum and escape by the anus. In such cases a careful examination of the patient will often reveal the origin of the pus, and will show that the case is not one of ordinary fistula in ano.

Treatment.—The treatment of this affection is similar to that of fistula in adults, consisting in the free division of all the tissues between the internal and the external opening of the fistula, and is accomplished in the following manner. A director having been introduced into the external opening of the fistula, the finger is introduced into the rectum, and when the point of the director is felt it is brought out of the anus. The superimposed tissues are then divided with a bistoury. The track of the fistula should next be carefully explored, to ascertain if there be any branching sinuses running off from it, and if such be found they should be freely laid open. The track of the fistula should now be touched with a solid stick of nitrate of silver and packed with iodoform gauze or lint saturated with carbolized oil, after which it is to be allowed to heal by granulation, the dressing being changed at intervals of a few days and the bowels being kept quiet for three or four days by the administration of a small quantity of opium.

In cases of incomplete external fistula the director should be introduced into the external opening, and, guided by the finger in the rectum, should be made to perforate the wall of the bowel at the point where it comes in close contact with it: the subsequent steps of the operation should be the same as those previously detailed.

In that variety of incomplete fistula in which there is only an internal opening, where the position of the fistula can be located by the presence of induration at some point about the anus, an incision having been made through the skin at this point, a director is introduced and made to enter the rectum, and its end is then brought out of the anus, the subsequent treatment of the case differing in no wise from that of complete fistula.

If it is found in any case of fistula that the internal communication is very high up in the rectum, and its division by the knife is considered unsafe by reason of the hemorrhage which might result, an elastic ligature may be introduced by means of an eyed probe and brought out at the anus, after which the ligature is tied and allowed to cut its way out, and the wound resulting is treated like that resulting from the division of the tissues by the knife.

FISSURE OF THE ANUS.

Fissure of the anus is an affection in which there exists in the mucous membrane of the anus a small linear ulcer, which is productive of great pain after the bowels have been moved.

This affection is much less frequent in children than in adults, but I feel sure that a careful inspection of the anal region of children who complain of pain at or after stool would show that its presence is not so unusual as is generally supposed. I have seen several cases of this affection in young children, and both Allingham and Curling mention cases which they have met with in quite young children.

Jacobi[1] thinks fissure of the anus a much more common affection in children than is generally supposed, and believes that many of the fretful children who sleep badly and cry constantly, and often present symptoms simulating those of vesical calculus, suffer from fissure of the anus. He quotes Kjellberg, who, at the Dispensary at Stockholm, among nine thousand and ninety-eight children found one hundred and twenty-eight cases of fissure of the anus; of the patients suffering from this affection sixty were boys and sixty-eight were girls, the majority were less than one year of age, and in seventy-three cases the patients were less than four months old.

---

[1] Intestinal Diseases of Children, p. 295.

Diagnosis.—The diagnosis of this affection is made from the pain which is experienced during or after stool, and from a careful inspection of the anus; the stool, also, may contain a few drops of blood, which would direct the surgeon's attention to the possibility of the existence of this affection; the rectum should at the same time be examined with the finger for the presence of polypus, which frequently coexists with fissure of the anus.

Treatment.—In children suffering with fissure of the anus the treatment required to effect its cure is less heroic than that so frequently required in adults suffering from the same affection,—namely, division or stretching of the sphincter.

These cases in the former class of patients can generally be successfully treated by the application of a twenty-grain solution of nitrate of silver to the ulcer, or by lightly touching its surface with the solid stick of nitrate of silver, and afterwards keeping the part well smeared with an ointment composed of thirty grains of iodoform to the ounce of vaseline, the bowels being kept in a soluble condition.

STRICTURE OF THE ANUS.

Stricture of the anus may be congenital, or may result from the contraction following wounds of this region, either accidental or resulting from operations in the vicinity of the anus.

The treatment of this condition resulting from congenital malformations has been already discussed. For cases of stricture of the anus arising from other causes the treatment is very similar, consisting largely in gradual dilatation of the contracted orifice, either instrumental or digital: if this fails to relieve the condition, a careful incision of the contracted parts should be practised, and subsequent dilatation employed for some time.

DIPHTHERIA OF THE ANUS.

This affection is occasionally seen in patients suffering from diphtheria of the pharynx and larynx. It usually occurs late in the disease, and only in cases in which the disease has profoundly impressed the system. In such cases the deposit of diphtheritic membrane may involve the anus and extend on to the buttocks, and to the vulva in female children.

The prognosis of this affection is extremely unfavorable. The few cases which have come under my personal observation have all terminated fatally, in spite of treatment. The treatment of this affection consists in the employment of such constitutional remedies as the surgeon considers appropriate. The local manifestation of the disease in the anal region may be dressed with iodoform or with a solution of the bichloride of mercury, one in two thousand to one in four thousand.

DISEASES OF THE RECTUM.

PROCTITIS.

Proctitis, or inflammation of the rectum, is not an infrequent affection in childhood, and may result from injury received from without, or from injury to the mucous membrane from the fæces or from materials contained in the fæces. It exists in two forms,—acute catarrhal proctitis and chronic catarrhal proctitis.

Acute Catarrhal Proctitis.—This is an affection in which the inflammatory symptoms are limited to the rectum. It is characterized by great tenesmus and the frequent passage of bloody mucus, at first mixed with fæces. Vesical irritation and œdema of the mucous membrane of the anus and lower portion of the rectum are generally present, and, as the result of this condition and of the constant straining, there is often observed a partial prolapse of the rectum.

Diagnosis.—Patients suffering from acute catarrhal proctitis present many symptoms in common with those of dysentery, but the abdominal pain and the constitutional symptoms of the latter affection are generally wanting.

Treatment.—A child suffering from this affection should be kept in the recumbent posture, and the bowels should be evacuated by the administration of a small dose of castor oil or of one of the saline cathartics, either the sulphate of sodium or of magnesium or some of the natural mineral waters. The diet should be restricted to milk, animal broths, or eggs.

If the tenesmus continue after the bowels have moved, a few drops of tincture of opium with starch-water should be injected into the rectum, or a rectal suppository containing

℞ Pulv. opii, gr. $\frac{1}{8}$;
Ext. belladonnæ, gr. $\frac{1}{6}$;
Iodoformi, gr. i;
Ol. theobromæ, q. s.,

may be employed; and if the patient shows signs of exhaustion, stimulants should be carefully administered.

The disease generally runs a short course, and under treatment the symptoms generally subside in a few days.

Chronic Catarrhal Proctitis.—This affection usually results from acute catarrhal proctitis. It is characterized by the discharge of mucus mixed with fæces, and by the absence of pain and tenesmus: in some cases, in which ulceration of the mucous membrane of the rectum exists, there may be in addition the discharge of a small quantity of blood and purulent matter with the mucus.

Treatment.—In the treatment of this disease the same precautions as regards diet should be observed as in cases of acute proctitis, and the bowels should be moved by the administration of a saline cathartic if the evacuations are not sufficiently free. The local treatment should consist in the use of suppositories of iodoform or the use of an enema of nitrate of silver, gr. $\frac{1}{4}$ to gr. i to water f℥i, which can be gradually increased in strength if it does not cause pain.

PERIPROCTITIS.

Periproctitis is an inflammation of the connective tissue surrounding the rectum, which may be the result of septic causes or direct injury, or may arise from the introduction of foreign matter through ulceration or perforation of the rectum. It may terminate in abscess or gangrene of the cellular tissue, with subsequent implication of the skin. Erysipelas may also attack this region, giving rise to erysipelatous periproctitis.

Treatment.—In this affection prompt treatment is required, and, as soon as the swelling and induration can be made out, free incision should be made through the skin into the cellular tissue in lines radiating from the anus. The wounds thus produced should be washed with a solution of bichloride of mercury, one in two thousand to one in four thousand, or with a solution of chloride of zinc, fifteen grains to the ounce of water, and should be dusted with iodoform and covered with a bichloride gauze or cotton dressing. If the parts have become gangrenous, the incisions should be carried into the living tissue and a charcoal poultice applied. The patient should be given a liberal diet, with alcohol and tonics.

ISCHIO-RECTAL ABSCESS.

Ischio-rectal abscess consists of a purulent collection in the loose cellular tissue surrounding the rectum, and is a most painful and serious affection: the part it plays in the causation of fistula in ano has been mentioned under that heading. This affection may result from injuries of the rectum either from within or from without, from phlebitis or periphlebitis of the hemorrhoidal veins, or from the escape of fæcal matter into the surrounding cellular tissue through perforating ulceration of the rectum.

Symptoms.—The symptoms of ischio-rectal abscess are throbbing pain and a sense of fulness in the lower portion of the rectum, the pain being measurably increased at the time the bowels are moved.

Diagnosis.—The diagnosis is made by a careful examination of the rectum with the finger, by which means the rectal wall may be found to bulge at a certain part, and there may also be observed swelling and œdema of the skin near the anus: palpation of this region will often reveal the presence of fluctuation.

Treatment.—The treatment of ischio-rectal abscess consists in early and free incision. It is generally conceded that there is no form of abscess which demands more prompt and free opening, for by this means the pain is quickly relieved and the danger of the formation of a fistula in ano is almost certainly avoided.

In opening these abscesses I think the practice of Allingham should be followed,—that is, to etherize the patient and place him in the lithotomy position. The cavity of the abscess should then be freely laid open by an incision through the skin, and the finger introduced into the wound to break down any secondary cavities or loculi: if it is found that there has been much burrowing of the pus, incisions should be made at right angles to the original incision so as to lay all cavities freely open. The cavity of the abscess is then to be washed out with a solution of bichloride of mercury, one in two thousand or one in four thousand, or with a solution of carbolic acid, one in forty. The wound is next to be carefully packed with lint saturated with carbolized oil, one in thirty, or with iodoform or bichloride gauze. An external dressing of gauze is finally to be applied to the wound and held in place by a T-bandage. The packing need not be disturbed until it becomes loose or soiled, and it then should be renewed in the same manner, the wound being allowed to heal by granulation. The bowels should be kept quiet for four or five days, and then should be moved by a gentle laxative. Under this method of treatment the cavity of the abscess is rapidly filled up, and a cure results without the formation of a fistula.

MARGINAL ABSCESS.

Marginal abscess, which consists of a circumscribed suppuration starting in the mucous follicles or from a fissure of the anal margin, is, I think, much more common in childhood than ischio-rectal abscess, and is a much less serious affection. This affection, although painful, is not a serious one, and it does not result in the formation of a fistula in ano.

Treatment.—The treatment of marginal abscess consists in making a free opening with a bistoury, in doing which the tip of the finger should be passed into the rectum to steady the abscess-cavity and make it more prominent before it is incised: the wound should then be dressed with lint saturated with carbolized oil. Prompt healing usually results.

ULCERATION OF THE RECTUM.

Ulceration of the rectum, aside from those cases in which it exists as a result of chronic dysentery or of chronic catarrhal proctitis, is not a common affection in childhood.

The treatment of this affection consists in the restriction of the diet and the regulation of the bowels, and in the local use of suppositories of iodoform or of injections of a solution of nitrate of silver, gr. ¼ to gr. i to water f℥i.

STRICTURE OF THE RECTUM.

Stricture of the rectum may result from congenital malformation of the rectum such as has been previously described, from the presence of growths, or from the contraction following wounds of the organ, the result either of accident or of operation. Bodenhamer mentions inherited syphilis as an occasional cause of congenital stricture of the rectum.

Treatment.—The treatment of this affection should consist in the gradual dilatation of the rectum, either instrumental or digital; if it be due to the presence of growths, their removal should be accomplished if possible; if it be due to syphilis, the treatment appropriate for this affection is indicated.

SYPHILIS OF THE RECTUM.

Lesions of the rectum due to inherited syphilis are certainly much less frequently met with in children than similar affections of the anus.

Ball[1] has described a case of gummatous infiltration of the coats of the rectum in a child ten years of age who at the same time exhibited well-marked symptoms of inherited syphilis, and the close resemblance of this case to the disease of the rectum described by Fournier resulting from the later stages of the acquired disease is pointed out. Oser, of Cracow,[2] has described two cases of gummatous infiltration of the intestines in children suffering from congenital syphilis.

Treatment.—The treatment of syphilitic lesions of the rectum presents no peculiar features, consisting in the administration of mercury or the iodide of potassium in the same manner as in the treatment of corresponding lesions in other parts of the body.

PROLAPSUS OF THE RECTUM.

Prolapsus of the rectum is that condition in which there is a protrusion of a portion of the rectum through the anus. It is recognized as presenting itself in three varieties:

1. The mucous membrane of the rectum above protrudes from the anus (partial prolapsus).
2. The entire thickness of the walls of the rectum is included in the prolapsus (complete prolapsus).
3. There exists an invagination as well as a prolapsus of the rectum.

Prolapsus of the rectum in some one of its varieties is a very common affection in childhood, and the frequency of its occurrence may be accounted for both on anatomical and on pathological grounds.

The looseness of the attachment of the submucous connective tissue to the walls of the rectum is a well-recognized anatomical fact, and probably plays an important part in the production of prolapsus of the rectum: this was clearly demonstrated by the experiment of Mollière,[3] in which inflation of the submucous tissue of the rectum in the dead subject produced protrusion of the mucous membrane through the anus. The straightness of the coccyx in children is said to favor the production of prolapsus of the rectum.

The great amount of straining which seems to be necessary to bring about a satisfactory evacuation of fæces in infants and young children is a factor in the production of this affection: this has been explained by Jacobi by the anatomical fact that in children it is not uncommon to find two or three angular flexures in the lower part of the colon.

---

[1] Loc. cit., p. 184.

[2] Hereditary Syphilis, Diday and Sturgis, p. 90.

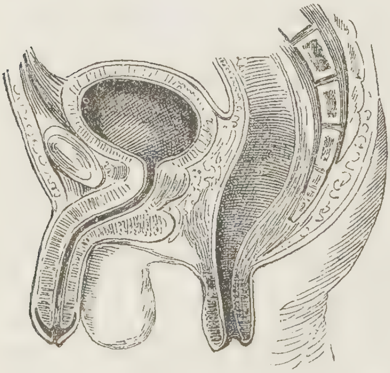
[3] Maladies du Rectum, p. 199.

The habit, so common with mothers and nurses, of placing the child upon the chamber utensil and allowing him to spend a large portion of time in that position, with a view to keeping him quiet and out of mischief, is certainly productive of this affection, and is a custom which cannot be too severely condemned.

The violent straining due to the presence of a polypus in the rectum, to seat-worms, to vesical calculus, or to a contracted prepuce, is frequently a cause of the production of prolapsus of the bowel. Improper diet or the custom of allowing children to eat at all times during the day, and as a result of this overfeeding the occurrence of a large number of passages, are common causes of this affection. That improper diet and overfeeding are causes of prolapsus of the rectum is very clearly impressed on my mind by the fact that at the Children's Hospital it is not an unusual occurrence to have children admitted to the wards for operation, with the history that they have suffered for some time with prolapsus of the rectum. In these cases, with rest in bed and with the regulated diet of the house, it often happens that the rectum fails to come down during defecation, and after a few weeks' stay in the hospital a cure is effected: this observation is confirmed by so high an authority as Mr. Holmes.

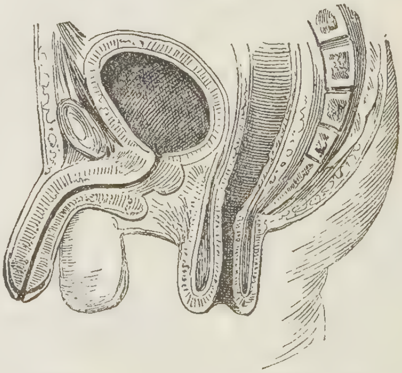
Symptoms.—The most marked symptom of this affection is the protrusion of a reddish-purple mass covered with mucous membrane during straining at defecation or urination. It is usually unaccompanied by pain, and it may undergo spontaneous reduction as soon as the straining efforts cease.

FIG. 13.



Partial prolapsus of the rectum. (After Mollière.)

FIG. 14.

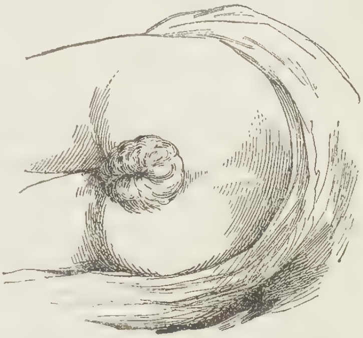


Complete prolapsus of the rectum. (After Mollière.)

If the prolapsus is of the partial variety, little inconvenience is experienced unless the prolapsed portion of the bowel is allowed to remain out for some time, when it may become congested or even ulcerated; and this is more apt to occur in cases of complete prolapsus. In the third variety of this affection obstruction of the bowels may exist as the result of the invagination of the prolapsed bowel; gangrene of the protruded mass has occurred in some cases, and death has resulted from this complication, as well as from peritonitis.

Diagnosis.—The diagnosis of prolapsus of the rectum is not difficult: the affection could be confounded only with hemorrhoids, an extremely rare disease in childhood, or with polypus. An examination of the rectum after the reduction of the mass will, if it be a case of prolapsus of the rectum, show the presence of no tumor, and the appearance of prolapsus of the rectum is so characteristic (Fig. 15)—the annular fold of tissue around the whole anus, with its depressed central orifice—that it is not difficult to distinguish it from either of the other affections.

Fig. 15.



Prolapsus of the rectum. (After Bryant.)

The greatest difficulty in diagnosis is likely to occur in cases of intussusception in children in which the intussusceptum may protrude from the rectum and closely resemble in appearance a case of prolapsus of the rectum: that this is possible is proved by the fact that such cases have been operated upon under the impression that they were cases of prolapsus of the rectum, the mistake being discovered only at the time of operation. The diagnosis of the latter affection from prolapsus of the rectum is not difficult if the surgeon makes a careful digital examination of the protruded mass, and also takes into consideration the previous history of the case, such as sudden pain and collapse, the occurrence of more or less obstruction of the bowels, and the passage of blood and mucus preceding the appearance of the tumor through the anus.

Treatment.—The treatment of this condition when the prolapsus of the rectum actually exists consists in returning the mass as soon as possible: this can generally be accomplished with ease by laying the patient across the knees and making gentle pressure with the fingers over the whole mass of the tumor for a few moments, to return the contents of the bowel and the fluids effused in the tunics, the central portion being pushed up first with the finger.

In recent cases little difficulty is experienced, but in long-standing ones, in which inflammatory effusion has taken place, there may be great trouble in returning the bowel, and it may prove necessary to administer an anæsthetic before the reduction can be satisfactorily accomplished.

When the reduction has been accomplished, a compress should be placed over the anus and held in place by a T-bandage, and the patient should be kept in the recumbent posture for a short time.

The preventive treatment of this affection consists in not allowing the child to have the bowels moved in the sitting posture; and prolonged straining on the chamber utensil should be absolutely interdicted. The child should be allowed to have the bowels moved only while in the recumbent posture, on the bed-pan, or on the side, or in the standing posture, and at the same time the nurse or mother should support the perineum and anus by two fingers placed one on either side of the anus, or should forcibly draw the skin of the buttock to one side while the child is passing the stool.

When prolapsus of the rectum depends upon the presence of a vesical calculus, or of a contracted prepuce, or of a rectal polypus, or of parasites, inducing great straining efforts, the removal of the cause will generally promptly effect a cure of this condition. I recently had under my care at the Children's Hospital a little girl three years of age who suffered from prolapsus of the rectum due to the straining induced by the presence of a vesical calculus, and a cure promptly followed the removal of the calculus.

The importance of looking carefully after the child's diet, which, as before mentioned, may be a factor in the production of this affection, should not be overlooked by the physician.

Enemata of cold water, or of astringent solutions, such as decoction of oak bark or solution of alum, or suppositories containing extract of nux vomica and ergot, may be employed. Of these applications I think the cold water enemata will be found the most satisfactory.

I am not aware that submucous or subcutaneous injections of carbolic acid or of ergotine, as recommended by Kelsey[1] or Vidal,[2] for the treatment of this condition in adults, have ever been tried in the treatment of prolapsus of the rectum in children, and I therefore should not recommend their employment. In cases of persistent prolapsus of the rectum in children, where the various palliative measures have failed to be followed by relief of the condition, I think the safest and, in my experience, the surest method of treatment is that recommended by Allingham, which consists in the application of nitric acid to the mucous membrane of the protruded gut.

This method of treatment is as follows. The child's bowels having been previously opened by the administration of a small dose of castor oil or by the use of an enema, the patient is anæsthetized, and the surface of the prolapsed bowel is carefully dried and cleansed of mucus by wiping it with absorbent cotton. The whole surface of the mucous membrane is then to be painted with nitric acid applied with a swab, care being taken not to allow the acid to come in contact with the adjacent skin. A pledget of oiled cotton or lint is now introduced into the central depression of the prolapsed mass, and by pressing it upward with the finger the mass is reduced. A pad is then placed over the anus, and the buttocks are brought together by broad strips of adhesive plaster. The bowels should be kept quiet for two or three days by the administration of a small amount of opium, and at the end of this time they should be opened by a laxative.

---

[1] Loc. cit., p. 115.

[2] Paris Médical, August 28, 1879.

In practice I have found that the introduction of the oiled cotton or lint into the prolapsed bowel at the time of operation is not necessary, as the child is apt to pass it by straining when he recovers from the anæsthetic: hence I generally omit its use, and merely coat the cauterized surface of the bowel with olive oil or vaseline before reducing it, the omission in no way affecting unfavorably the result of the operation.

The prolapsus may recur with the first few passages, but a permanent cure is generally effected by one application of the nitric acid; should this not be the case, the cauterization may be repeated in a few weeks. I have never failed to see, in prolapsus of the rectum in childhood, a second or third application bring about a cure.

The use of the actual cautery, the ligature, or the clamp and cautery has been recommended, but is attended with danger in cases of complete prolapsus of the rectum in which the peritoneum is included in the mass, and, although they have been used with success in the treatment of this affection in adults, I have never seen a case of prolapsus of the rectum in childhood in which their employment seemed to me to be justified, and in which the simpler and safer procedure—namely, cauterization with nitric acid—failed to give a satisfactory result.

In long-standing cases of prolapsus in which invagination has occurred and the patient is suffering from obstruction of the bowels, if the prolapsus cannot be reduced under ether, the only operation which holds out any prospect of success is the establishment of an artificial anus by a laparo-colotomy, which should preferably be made in the left groin. In such a case, if the child survive, at a later period attempts may be made to close the fæcal fistula in the groin, as soon as the invaginated portion of the gut has been removed by sloughing or other means, thus allowing the fæces to escape through their natural channel.

HEMORRHOIDS.

Hemorrhoids are vascular tumors occupying the lower portion of the rectum, arising from a dilatation or proliferation of the blood-vessels. They may be either internal or external, and accordingly may be covered by mucous membrane or by skin. This is a very rare affection in childhood: when it does exist, the hemorrhoidal tumors generally consist of dilated veins, and they are apt to occur in children of a weak and delicate constitution. A few cases have been reported: Allingham[1] mentions a case of venous hemorrhoids which came under his observation in a child three years of age; Ball has seen several cases occurring in quite young children; F. Ogston[1] reports a case in which the disease appeared to be congenital; and my own experience has been limited to one case occurring in a child five or six years of age.

---

[1] Loc. cit., p. 75.

Symptoms.—The symptoms of hemorrhoids in children are very similar to those of the same affection in adults, consisting in the protrusion of the hemorrhoids and occasional bleeding at the time of defecation.

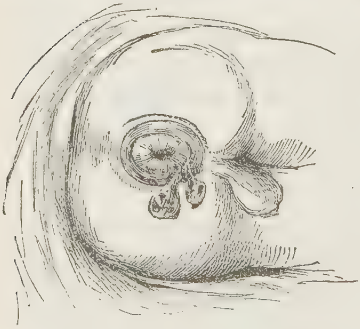
Diagnosis.—From the symptoms presented, the physician would possibly be justified in suspecting the presence of prolapsus of the rectum, but the diagnosis can readily be made by a careful local examination.

Treatment.—The treatment of hemorrhoids in children consists in the administration of iron and cod-liver oil, the local use of astringent ointments, and regulation of the action of the bowels: under this treatment a cure will generally result. If, on the other hand, the tumors continue to bleed and be protruded at defecation, the surgeon can have recourse to the injection into the hemorrhoids of a twenty-five-per-cent. or fifty-per-cent. solution of carbolic acid in glycerin, or to the use of the ligature or of the clamp and cautery.

POLYPUS OF THE RECTUM.

Polypus of the rectum is not an uncommon disease in childhood. It is usually characterized by the presence of a follicular tumor springing from the mucous membrane of the rectum, to which it is attached by a narrow pedicle at a point an inch or an inch and a half above the anus. The follicular or adenoid polypus is the variety of growth which is most commonly seen in children, and closely resembles in its structure the normal mucous membrane from which it has its origin, although its glands are more abundant and are often more branched and convoluted. The fibrous polypus, composed chiefly of fibrous cellular tissue, also has been met with, and very rarely cystic polypus; of the latter variety Cripps[2] reports a case occurring in a boy nine years of age. Disseminated polypi of the adenoid variety have also been observed in young persons; Mr. Thomas Smith[3] has recorded three cases of this affection occurring in members of the same family, and Cripps[4] mentions cases of this nature in which considerable areas of both the rectum and the colon were studded with these growths.

Fig. 16.



Polypi of the rectum. (After Ball.)

The tumors may be single or multiple (Fig. 16), and are of a bright-red color when first extruded, but become darker and more venous in appearance after they have been protruded some time and their circulation has been interfered with by the constriction of the sphincter: the length of the pedicle may vary from half an inch to two or three inches.

---

[1] London Lancet, May 12, 1886.

[2] Loc. cit., p. 281.

[3] St. Bartholomew's Hospital Reports, vol. xxiii. p. 225.

[4] Loc. cit., pp. 275, 276.

Eustace Smith says that polypus of the rectum is rare in children under ten years of age; Bokai found twenty-five cases of this growth in sixty-five thousand nine hundred and seventy patients. Jacobi[1] says that he sees from one to three cases annually among five hundred children.

Symptoms.—The presence of a rectal polypus gives rise to a sense of fulness and distress in the lower part of the rectum, and there may be expulsive efforts with tenesmus. The escape of glairy or bloody mucus or of blood is a very constant symptom, and in children this alone is presumptive evidence of the presence of this growth.

Diagnosis.—The diagnosis is not difficult, as the polypus is apt to present at the anus or protrude from it during defecation; it is likely to be confounded only with hemorrhoids or prolapse of the rectum, and a careful examination with the finger will disclose the presence of the pedicle to which the growth is attached. It is well to give an enema just before the examination, and when it passes the growth is apt to be brought to the lower part of the rectum, or may present at the anus. It is also advisable to introduce the finger well into the rectum, and to make the examination of its walls as the finger is withdrawn with a sweeping motion, by which means the pedicle of the polypus may be hooked upon the finger.

It is probable that in many cases polypi undergo a spontaneous cure by the separation of their attachments from the bowel, and are passed with the stool, all symptoms depending upon their presence disappearing upon their expulsion: a number of such cases have been reported.

Treatment.—The treatment of polypus of the rectum is simple and satisfactory. The tumor may be seized with the fingers or forceps and twisted off, and the stump touched with the solid stick of nitrate of silver, or with nitric acid: the only disadvantage of this method is the possibility of troublesome hemorrhage.

I think the best and safest method is to seize the polypus and draw it out so as to expose its pedicle, and to encircle this with a ligature close to the mucous membrane, care being taken not to make sufficient traction to invert the wall of the rectum, which might then be included in the grasp of the ligature. The ligature should next be firmly tied, and the tumor removed by dividing the pedicle in advance of the ligature. If a number of polypi exist, the same procedure is repeated for each growth.

ANGEIOMA OR NÆVUS OF THE RECTUM.

Nævus of the rectum is an extremely rare affection, and very few cases have been observed. Mr. Arthur E. Barker[2] has published a case of this nature, and Mr. Howard Marsh has reported the case of a girl ten years of age who suffered from rectal hemorrhage and in whom an examination revealed a nævoid growth in the lower part of the rectum.

---

[1] Intestinal Diseases of Children, p. 286.

[2] Med.-Chir. Trans., vol. lxvi.

The principal symptom consequent upon this disease would be hemorrhage, and some difficulty might be experienced in diagnosing it from hemorrhoids.

Treatment.—The treatment of angeioma of the rectum consists in the use of a ligature to strangulate the growth, or in the application of nitric acid or of Paquelin's cautery; the latter means was successfully employed in the case reported by Mr. Marsh.

MALIGNANT DISEASE OF THE RECTUM.

Malignant disease of the rectum in childhood, in the form either of cylindrical-celled carcinoma or of sarcoma, is very rarely met with. Allingham[1] reports the case of a boy thirteen years of age who suffered from cancer of the rectum, and another case in a lad of seventeen years; and a few similar cases have been reported by Quain, Cripps, and other observers.

Diagnosis.—The diagnosis of this affection is to be made from the non-malignant growths of the rectum, and will depend largely upon the presence of the peculiar cachexia of cancer. The prognosis is extremely unfavorable.

Treatment.—The treatment of malignant disease of the rectum consists in the excision of the growth if its situation is favorable for such a procedure; or linear rectotomy, which consists in freely dividing the growth, together with the lower portion of the rectum, including the sphincter, may be practised, with at least temporary benefit; or, if excision is not possible, owing to the fact that the growth involves a high portion of the rectum, and if symptoms of obstruction of the bowels are present, colotomy should be performed.

WOUNDS OF THE RECTUM.

Wounds of the rectum may be caused by bodies introduced through the perineum or the anus or by substances which reach the rectum through the alimentary canal. They may be lacerated, incised, or punctured. Severe lacerated or punctured wounds may result from patients falling upon sharp bodies which enter through either the perineum or the anus, or from sharp fragments of broken bones of the pelvis, causing in many cases extensive laceration of the parts about the rectum as well as of the rectum itself, and these wounds may be complicated by injuries of the bladder, vagina, or peritoneum. Many cases of severe punctured or lacerated wounds of the rectum have resulted from the careless or forcible introduction of the nozzle of the enema-syringe. The laceration of this organ in children who have been subjected to unnatural intercourse should also be mentioned. The most common varieties of incised wounds of the rectum are those resulting from operations upon that organ or from the accidental incision of the bowel in the operation of lateral lithotomy.

---

[1] Loc. cit., p. 230.

Among the unusual forms of injury to the rectum might be mentioned a recently reported case in which the injury partook of the nature both of a burn and of a wound, a blacksmith having thrust a red-hot bar of iron into the rectum of a boy who was sitting on a grating over his shop, the bar entering the bowel for several inches and inflicting a distressing burn which proved fatal in a few days.[1] Bodies also which have passed through the alimentary canal have been known to produce serious injuries of the rectum.

Prognosis.—Incised and lacerated wounds of the rectum which do not involve the bladder or peritoneal cavity generally heal very promptly, as is seen in wounds made by the surgeon in operations upon this organ, or in the accidental wounds occurring in the lateral operation for stone in the bladder; but in deep lacerated wounds in which the above complications exist, and in punctured wounds in which there is not adequate drainage, the prognosis is not so favorable. In lacerated and punctured wounds of the rectum the greatest danger results from hemorrhage and cellulitis, and when they are complicated by visceral injury or wound of the peritoneum the risks of urinary infiltration and peritonitis may be superadded, rendering them a most grave class of injuries.

Treatment.—The treatment of the simplest variety of incised or external lacerated wound of the rectum, which involves only its lower portion, consists in controlling the bleeding by the application of ligatures to the bleeding vessels, in washing the wound thoroughly with a solution of the bichloride of mercury from one in two thousand to one in four thousand, in dusting the wound with powdered iodoform, in providing for free drainage by the introduction of a drainage-tube, and in bringing the edges of the wound together with catgut sutures. A gauze dressing should then be applied, and the bowels kept quiet for a few days: under this treatment repair usually takes place promptly.

In punctured or internal lacerated wounds of the organ which do not extend high enough to involve the bladder or the peritoneum, it is considered advisable, in order to secure free drainage, to convert the internal punctured or lacerated wound into an open wound by the division of all the tissues, including the external sphincter and the skin, as would be done in the case of internal fistula. The wound should then be washed with a bichloride-of-mercury solution, packed lightly with iodoform gauze, and allowed to heal by granulation, the dressings being changed only as often as they become soiled. In cases complicated by a wound of the bladder perineal cystotomy has been recommended, to provide for the free escape of urine: in the case of a boy who suffered from a wound of this nature Mr. Bryant[2] adopted the above procedure, with a favorable result. Free drainage is also to be secured by division of the anal sphincter, and by the introduction of drainage-tubes if necessary. If there is evidence of puncture of the peritoneum, with injury of the contained viscera, the surgeon should perform laparotomy, and wounds of the viscera, if found, as well as the rent in the peritoneum, should be closed by sutures.

[2] Medical Times and Gazette, May 25, 1878.

FOREIGN BODIES IN THE RECTUM.

Foreign bodies may enter the rectum from the upper part of the alimentary canal or may be introduced through the anus: in the former case they may consist of masses of fæcal matter which have become inspissated or of substances which have been swallowed and have been arrested in their passage through the rectum. The greatest variety exists in the foreign bodies which have been introduced, either by accident or by design, through the anus into the rectum.

Symptoms.—The symptoms of a foreign body impacted in the rectum are pain, ineffectual attempts at defecation, and the passage of mucus or blood-stained mucus.

Diagnosis.—The diagnosis of the condition producing these symptoms can be made by a careful exploration of the rectum with the finger, which will enable the surgeon to assure himself of the presence, the character, and the exact location of the foreign body.

Treatment.—The treatment of foreign bodies impacted in the rectum consists in their removal with the least possible injury to the walls of the organ. To do this satisfactorily it is well first to anæsthetize the patient and then to inject into the rectum a few ounces of olive oil. When the character and the position of the body are ascertained, it may be dislodged by the finger and removed by means of forceps. Large masses of inspissated material may require fragmentation before their removal can be satisfactorily accomplished. Where the body is irregular in shape, or possesses sharp edges or angles which may cause injury to the lower part of the rectum or anus, the introduction of retractors or of a bivalve speculum and full dilatation of the anus and of the lower portion of the rectum will greatly facilitate its removal without injury to the rectal walls.

If after removal of the foreign body it is found upon examination of the rectum that ulceration has resulted from its presence, a solution of nitrate of silver, ten grains to the ounce of water, should be applied to the ulcerated surface, the patient kept in bed, the diet restricted, and suppositories containing iodoform introduced into the rectum. The possibility of stricture following this condition should not be lost sight of, and if cicatricial contraction supervenes it should be treated by the use of bougies.

COLOTOMY.

By JOHN H. PACKARD, M.D.

THE operation of colotomy, or the making of an opening in the wall of the large intestine,—an artificial anus,—is occasionally required in children for the relief of congenital malformations of the rectum, in order to give free exit to the contents of the bowel. I am not aware of any recorded instance of its performance in childhood for any other reason. When the gut terminates in a blind pouch, the condition is one which, if not speedily remedied, will destroy life: so that in such cases operative interference is needed within a very few days of birth, and the earlier it is resorted to, the better.

The subject of these congenital malformations, and of their varieties, is elsewhere discussed: we are here concerned only with the operations to be contemplated when the bowel cannot be reached and opened through the perineum.

When in a newly-born child this condition of things is found to exist, it becomes the duty of the attendant to inform the parents of its very grave significance, and to propose to them an operation, as affording the only possible chance of saving the infant's life. The opinion has been very strongly expressed by some surgical writers of high authority that it would be better to let a child die than to prolong its existence in the loathsome and distressing state which they think must be brought about by the formation of an artificial anus. Such an idea is not, however, borne out by experience; in many cases, and probably in all by proper care, the child can be made as comfortable and kept as clean as if the fæces were discharged by the natural channel. And it may be questioned, even if this were not so, whether the rule of professional conduct should not be to preserve life under any circumstances. Certainly the responsibility of declining interference should be placed upon the friends.

Moreover, the performance of this operation of opening the colon and giving exit to its contents need not be regarded as a finality; it may be done, and perhaps always should be done, with a view to further measures for the establishment of the natural passage, after which the closure of the artificial orifice may be attempted.

Practically, there are two points to be considered as eligible for the opening of the colon in these cases. One is the descending portion of the gut, reached by an incision in the left loin; the other is the sigmoid flexure, accessible from one or the other groin, usually the left. (In the adult the cæcum may be opened in the right groin, or the ascending colon in the right loin; but neither of these procedures is proper in cases of imperforate rectum, since the large portion of bowel below the site of operation would constitute a cul-de-sac in which fæcal matters would accumulate and give trouble, while there would be no chance for further effort at establishing the natural passage by means of the opening thus made.)

The chief peculiarity of these operations in children consists in the small size of the parts, and the delicacy of the tissues, making the manipulations difficult; moreover, the rules laid down for their performance in adults will not apply here.

Colotomy in the left loin, often called Amussat's operation, has for its object the exposure and opening of the posterior wall of the descending colon, avoiding, if possible, interference with the peritoneum.

Anæsthesia is not necessary in any of these procedures, and in the case of a very weakly child might add an element of shock which would be very undesirable. If, however, a strong child should by its cries and struggles interfere with the making of a careful examination, a few whiffs of ether may be given to quiet it.

Antiseptic precautions ought certainly to be observed. It is true that the escape of meconium will subsequently make it difficult to keep the wound clean, but the early healing of all but the fistulous orifice will be favored, and, which is very important, the risk arising from any accidental interference with the peritoneum will be greatly diminished.

The child should be carefully wrapped up in suitable flannels, only the part to be operated on being exposed. It should be laid upon a table of proper height, on a pillow, in such a position as to make the left loin prominent,—viz., on its right side, but turned somewhat on its face. A good light is absolutely essential.

The instruments required are a scalpel, a probe-pointed bistoury, dissecting- and artery-forceps, tenaculum, scissors, grooved director, small retractors for keeping the edges of the wound apart, fine catgut ligatures, needle-holder and curved needles, and silk and silkworm-gut for sutures. All these, thoroughly sterilized, and placed in carbolized water, should be within reach either of the operator or of a skilled assistant.

My own rule, which I have always found reliable, is to begin at the upper and outer corner of the quadratus lumborum muscle,—a point easily found,—and to cut the skin downward and outward in a line at an angle of forty-five degrees with a vertical one, nearly to the crista ilii. I divide the skin obliquely, so that one edge is bevelled at the expense of its outer surface and the other at the expense of its inner,—this plan making the subsequent closure of the wound more complete, and favoring healing, especially as the access of fæcal matter to the cut surfaces is rendered well-nigh impossible. The deeper tissues are divided layer by layer, to the same extent as the incision through the skin: this is very important, as otherwise the operator would finally find himself working at the bottom of a funnel-shaped hole, and at a great disadvantage. A layer of firm fascia is soon reached, which being divided, a mass of fat is seen, beneath which the colon will be found. Sometimes a few fibres of the transversalis muscle are cut at the outer edge of this fascia. During this dissection, all vessels which may spring should be carefully tied with fine catgut.

By means of the retractors, the wound is now held open, while the surgeon works through the fat with the knife-handle and his finger. Occasionally the outer edge of the kidney is in the way, and must be cautiously pressed inward (towards the median line). If distended with meconium, the bowel will presently be felt as a smooth, rounded, doughy mass, and may be exposed to view. It is of a dull grayish-yellow color, with the dark-green meconium showing through it; often one of the longitudinal muscular bands is also seen.

On satisfying himself that it is the bowel which he has before him, the surgeon takes a small curved needle, armed with a silk ligature, and carries it through the wall of the gut just above the middle of the exposed portion, bringing it out again at a point an eighth of an inch distant, and on the same level; he then repeats the process half an inch lower down, and thus has two loops of thread by which control of the gut-wall is secured. Drawing it outward, and giving the ends of one of the loops to an assistant, the wall may be made tense, and divided with the point of the scalpel, upon which meconium will at once escape. The wound may be protected from contact with this material by means of a flat aseptic sponge or a layer of sublimated cotton.

The size of the opening to be made must be a matter of judgment with the operator. If too small, it will be apt to contract, and will be insufficient for the escape of fæcal matters. If too large, the mucous membrane will prolapse through it, and is apt to become very sore; besides which, there will be too free and constant discharges, making it almost or quite impossible to keep the child clean.

The edges of the opening in the gut are now everted, and carefully fastened to the skin by four or six points of suture with silk thread; the remainder of the wound above and below is then accurately closed with silkworm-gut sutures, carried deeply, so as to effect entire apposition of all the tissues. Iodoform is next dusted over the surface, and a thick layer of sublimated or borated cotton applied, kept in place by a flannel binder.

The operation now described does not involve any special danger. In the only instance in which I have resorted to it in the living child, there was no difficulty whatever; but a few hours afterwards, copious oozing of blood ensued, and was checked only by the application of tannin upon cotton, several other measures having been tried in vain. The overlapping of the gut by the kidney may be a source of some embarrassment, but has never, so far as my knowledge goes, prevented the surgeon from proceeding. A more formidable hinderance may occur in the difficulty of finding the bowel, which may be due to either of two causes,—the existence of a wide mesocolon, like the mesentery, so that the colon floats out in the abdominal cavity instead of lying embedded in the circum-renal fat, or the absence of fæcal contents, the tube being empty and contracted. The latter condition has been found in several instances to be due to atrophy affecting the whole of the large intestine. In the former case, if the mass of the distended colon were made out by its being crowded back by pressure on the belly in front, the opening and securing of its wall might be effected in the same way as described above, the peritoneum being slit, and the bowel drawn through the orifice. Should this be done, care should be taken in the suturing to insure accurate and close coaptation of the two serous surfaces.

Ordinarily the peritoneum is in no danger in an operation of this kind; but if by any awkwardness or mischance it should be nicked or torn, the edges of the rent should be at once caught up, and a fine catgut ligature applied around the part, so as to close it like the drawing-string of a bag.

Colotomy in the groin, often called Littre's operation, or inguinal colotomy, has for its object the opening of the colon in its sigmoid flexure. The remarks made as to anæsthesia, antiseptics, and instruments, in reference to the operation in the loin, are applicable here, and need not be repeated.

Any one familiar with the anatomy of the adult only, if asked in which groin he would expect to find readiest access to the sigmoid flexure, would unhesitatingly reply, in the left. But in 1858 M. Huguier made to the Académie Impériale de Médecine in Paris the statement that the condition of the gut in new-born children was such that the sigmoid flexure occupied the right groin, and hence that the operation should be done on this side rather than on the left. To test the correctness of this view, careful researches were made by several observers, and the results are given by Giraldès.[1] He himself found, in one hundred and thirty-four autopsies on children, the sigmoid flexure at the left side in one hundred and fourteen; he collated fifty instances of Littre's operation, in all of which this was the case, as also in thirty autopsies on children operated on for atresia ani. Bourcart found it so in one hundred and seventeen out of one hundred and fifty, and Curling in eighty-five out of one hundred cases. The sigmoid flexure was thus on the left side in three hundred and ninety-six out of four hundred and sixty-four cases, or about eighty-five and one-third per cent. But, strange as the assertion may seem, it does not appear that in the other sixty-eight cases the sigmoid flexure, or an available portion of it, could not have been reached from the left side as well as from the right.

Goéde[2] advocates Huguier's view, and gives a very elaborate theory as to the reasons why such a disposition of the intestine should obtain. It seems to me, however, that the matter is susceptible of a simple explanation. The comparatively very small size of the pelvis being remembered, the thinness of the intestinal wall, and the accumulation of meconium during intra-uterine life, it will be obvious that the large bowel will be loaded to distention, and that the sigmoid flexure must be swollen, the arc of its curvature being increased, and the mass pressing in the direction of least resistance. In this way it may be that a large part of the sigmoid flexure may be met with in the right groin, but its lower portion must run backward to its anchorage in front of the sacrum. With antiseptic precautions the peritoneum, being necessarily opened on whichever side the operation is done, may be explored with an antiseptic finger, and the bowel found.

---

[1] Dict. de Méd. et de Chir. pratiques, 1865, tome ii., art. "Anus."

[2] Jour. de Méd. et de Chir. pratiques, tome xlix., December, 1878.

My own preference, therefore, would always be for the left groin.

The child is to be laid on the back, the thigh very slightly flexed on the trunk. An incision about an inch and a half in length is made parallel with Poupart's ligament, and about half an inch above it, beginning near the anterior superior spine of the ilium. Layer by layer the tissues are divided to the same extent, until the transversalis fascia is reached and opened, when the peritoneum will be exposed. Any vessels which spring are to be securely tied with fine catgut. The peritoneum being nicked and divided on a director, the operator passes a clean and aseptic finger into the abdominal cavity to feel for the gut. If this bulges into the wound, it is at once caught; if not, when found it is coaxed down, pushing the other intestines out of the way. As soon as it comes into the wound, it is caught with a hook or with toothed forceps, and two silk sutures passed through the wall, so as to obtain control of it. By means of the threads it is now drawn well through the wound, and four silver-wire or silk sutures are passed, two through all the tissues at each edge of the wound, and then through the wall of the gut and out on its exposed surface. Between these, as nearly as possible at the centre of the exposed surface, the gut is now opened, and the edges of the opening are at once caught with forceps. Extreme care must be taken to prevent the escaping meconium from finding access to the peritoneal cavity. The silk or silver-wire sutures are now to be carefully secured by tying or twisting, additional points of suture between the skin and bowel-edge being placed if necessary. The remainder of the wound is now accurately closed with sutures of silkworm-gut. I think it is better to suture the deeper tissues and peritoneum with fine catgut first, and to let the silkworm-gut sutures secure the superficial tissues merely.

Finally, iodoform and borated or sublimated absorbent cotton are applied, as in the case of the lumbar operation.

Colotomy in the right groin does not differ in any important particular from the operation just described. In the adult it is sometimes resorted to with the purpose of opening the cæcum, the peritoneum being left intact; but in the infant such a procedure would be of necessity a mere palliative, and open to objections already stated.

The question of the comparative advantages of the two methods of opening the colon, which have now been described, naturally presents itself. Should the operation in the loin be preferred, or that in the groin?

One advantage offered by the lumbar incision, and the chief, is that, as a rule, the bowel can in this way be reached and opened without interfering with the peritoneum. This is a matter of less moment at the present day than it was in pre-antiseptic times. A more practically important point is that in case of failure to find the bowel at this spot, the wound can be at once closed, and a fresh attempt made elsewhere. Again, unless there be a wide mesocolon, this part of the gut is much more firmly fixed than is the sigmoid flexure.

On the other hand, the dissection required to expose the colon in the loin is deeper, and really more difficult, than in the groin. And the very fact of the depth and fixation of the bowel makes it less easy to deal with. Should further measures be contemplated, with a view to establishing an anus at the normal point in the perineum,[1] the lumbar opening affords less facility for so doing than the inguinal. Finally, in the event of the child's surviving to the age when it should attend to itself, an artificial anus in the loin would be much less conveniently placed than one in the iliac region.

In the inguinal operation the peritoneum is of necessity opened, and this fact, in spite of all antiseptic precautions as to the procedure itself, involves some risk of the entrance of meconium into its cavity. Such a mischance, which must inevitably prove fatal, cannot always be guarded against, and may have induced the peritonitis which is noted as a frequent cause of death in these cases.

The inguinal operation, however,—although, from what may be called a sort of traditional superstition among surgeons, it is looked upon as more formidable,—is in reality easier of performance than the lumbar. Some portion of bowel is always to be found here, and generally that which is wanted. Explorations downward for the purpose of establishing an anus in the perineum are much more readily made, since the distance to be traversed is much less than from the loin, and the route to be followed is less tortuous.

When the little patients survive, there are two annoyances to be feared, whichever operation has been chosen. One is the prolapse of the bowel through the artificial opening, the mucous membrane forming a projecting villous mass, with an orifice at either side, one leading into the upper portion of the tube, the other into the lower portion. This can be obviated only by proper pads held in place by bandages or adhesive plasters.

The other, and really the more troublesome, condition is the narrowing of the orifice so that the escape of fæces is hindered. Division of the tissues with the knife, under such circumstances, should be very cautiously done, if done at all. A safer plan is to use some means of dilatation, as a sponge or laminaria tent, or plugs, like sections of rectal bougies, gradually increasing in size until the opening is made sufficiently free. Laxatives and injections must, of course, be used if the fæcal mass is too firm to be readily expelled. The process of dilatation may need to be repeated again and again, as the contraction recurs.

---

[1] A case of this kind, in which, considering the unfavorable circumstances surrounding it, a really brilliant success was obtained, was reported by Dr. W. H. Haynes, of New York, in the *American Journal of the Medical Sciences* for July, 1884. The child, at eleven months of age, was in good condition locally, in spite of neglect on the part of its parents: its death, which took place some time afterwards, was ascribed to convulsions incident to teething.

When we look at the published records and statistics of these operations, it is clear that this is not one of the fields in which surgery has been brilliantly successful. Very possibly in many cases the malformation is merely a local expression of a general deficiency of developmental power, and the children so affected are in other respects wanting in vigor. Certain it is that very few of them pass the period even of infancy.

The most available statistics on this subject are not recent. They are those of Curling[1] and Giraldès.[2]

Curling gives a table of one hundred cases, operated on in various ways; those which concern us here are the twenty-three in which colotomy was performed. Of these, the gut was opened in the loin in eight, with two successes; in the remaining fifteen the inguinal operation was done, with ten successes. Both of the successful lumbar operations were performed by Amussat; the subject of one was known to be living and well at the age of seven years, but the other was reported to have died at about two months.

Giraldès gives a table of thirty-four cases, all of them inguinal colotomies. Of the whole number, twenty-three died under one year of age; and of these, only three survived a month or more. One is said to have reached the age of fourteen months, and three that of two years. (One child, operated on at the age of four years, lived eight months afterwards.)

Among the remaining seven, Rochard, of Brest, is to be credited with one, the subject of which lived five years; Miriel, also of Brest, had one patient (included above) who lived two years, one who reached fourteen years, and another nineteen; two other of his patients attained adult age, one dying at twenty-two, the other at forty. A child operated on by Duret, also of Brest, grew up, and lived to the age of forty-three. The longest period of life secured in this way was in a case of Serrand's,—forty-nine years.[3]

Miriel's successes, referred to above, are unparalleled in the experience of any other surgeon, so far as any published records show; and it is fair to conclude that they stand alone. A very large number of reports of isolated cases may be found scattered over the pages of medical journals, but in the great majority of them only a brief extension of life has been secured. Some of these patients, indeed, are lost sight of by the operators, and may have lived to grow up; but it would be strange if there were many such who failed to attract the observation of medical men in their later years, in which case the fact would almost certainly be made known to the profession.

---

[1] Medico-Chirurgical Transactions, vol. xliii., 1860.

[2] Dict. de Méd. et de Chir. pratiques, Paris, 1865, art. "Anus artificiel."

[3] These tables cannot be combined, partly because they overlap, some of the same cases occurring in both, but also because there are as to these some minor discrepancies which, not having access to the original reports, I have been unable to reconcile.

When we try to investigate the cause of the very large proportion of deaths among children operated on for malformations of the rectum (no matter what the special lesion or the procedure adopted), we find that in very many of the cases it is stated that the patients did well for a time, and then began to fall away, dying from exhaustion; in others we find that they are said to have succumbed to some of the milder diseases incident to childhood. And therefore it seems to me reasonable to suppose that these malformations may be properly regarded as not only mere local defects of development, but also, or perhaps as such, as significant of a constitutional want of force, so that the subjects of them are prone to pass into an adynamic condition, or, when attacked by the diseases of childhood, to lack the power to make a successful resistance.

The condition of imperforation of the rectum is a certainly fatal one: the operation of opening the colon does not in itself involve any serious risk; it presents no great difficulty to any one with proper anatomical knowledge and average surgical dexterity; and it will at least afford palliation of the sufferings of the little patient. An opportunity may perhaps be made in this way for further measures, looking to the establishment of an anus in the normal position.

Under these circumstances, it seems clear that the resort to operative interference is not only justifiable, but also imperatively indicated. The best chance of success, in the light of past experience, is in the operation in the left groin; and it should be done at the earliest practicable moment. Such procedures can hardly be instituted with sanguine expectations of brilliant results, but it is well worth while to undertake them merely with the object of alleviating suffering.

DISEASES OF THE PANCREAS,

AND

THEIR OPERATIVE TREATMENT.

By N. SENN, M.D.

TOPOGRAPHICAL ANATOMY OF THE PANCREAS.

FOR a correct interpretation of the signs and symptoms of the different diseases of the pancreas, and for an accurate understanding of the relations of this organ to surrounding parts in their surgical treatment, it becomes necessary to refer to the topographical anatomy of the pancreas. The pancreas is a tongue-shaped gland placed transversely in the abdomen, at a point opposite the first lumbar vertebra, behind the stomach, reaching from the hilus of the spleen to the concavity of the duodenum. Its right end, termed the head, is embraced by the curvature of the duodenum, whilst its left or caudal extremity is in contact with the spleen. After opening the abdominal cavity in cadavers, it can be distinctly felt as a firm body through the walls of the stomach. The organ is made accessible and exposed to sight by cutting the ligamentum gastro-colicum transversely, and by pushing the stomach upward and the transverse colon downward. In the saccus epiploicus, which has now been opened, the gland is seen in front of the large vessels. It presents three surfaces for examination. The anterior surface, somewhat concave, is in contact with the stomach throughout its entire extent, but separated from it by a covering from the omental bursa which renders the surface smooth and well adapted for the free movements of the stomach. The posterior surface is separated from the spine by the vena cava, the aorta, the superior mesenteric artery and vein, the pillars of the diaphragm, and, towards the liver, the vena porta, as well as by numerous lymphatic vessels and glands, all of which are firmly connected with this surface, and the spine, by connective tissue. To the left of the vertebral column it is attached in the same manner to the left suprarenal capsule, kidney, and renal vessels. The superior mesenteric artery and vein are embraced by the substance of the gland, so as sometimes to enclose these vessels in a complete canal. The inferior surface is narrow and directed towards the transverse colon, the right end resting on the junction of the duodenum and jejunum, and the left on the extremity of the transverse colon. The intervening middle portion of the inferior surface has a special peritoneal covering derived from the lower layer of the mesocolon. Along the posterior surface and upper border of the gland are placed the splenic artery and vein, both pursuing a tortuous course from right to left. The cœliac axis is above the pancreas. The common bile-duct is in close relation to the head of the gland, passing down along its posterior surface, and is generally received into a groove or canal in its substance.

The common pancreatic duct, or canal of Wirsung, is widest near its entrance into the duodenum, where it is from one-twelfth to one-ninth of an inch in diameter. Before its termination it unites with the common bile-duct in the wall of the intestine, at the junction of the second and third portions of the duodenum, between three and four inches below the pyloric orifice of the stomach. The lower extremity of the head, where it curves behind the mesenteric artery and vein, is sometimes marked off from the rest, and is then called the *lesser pancreas*, with a special duct which joins the common duct in the substance of the head of the pancreas. The pancreas receives its blood-supply from the superior and inferior pancreatico-duodenal branches of the hepatic and superior mesenteric arteries. The venous return takes place through the splenic and superior mesenteric veins. The nerves are derived from the solar plexus.

ACCESSORY PANCREAS.

The pancreas, like many other glandular organs, sometimes presents rudimentary duplicities, and it is necessary to call attention to this fact for the purpose of considering the possibility of the origin of a pancreatic cyst from one of these appendages. Rokitansky mentions, as an exceedingly rare occurrence, duplicity of the pancreas and excessive development of accessory appendages. A frequent variety is represented by the head of the gland,—the *pancreas minus*,—the duct of which usually terminates in the common duct, but sometimes, as was first ascertained by Winslow, takes an independent course and empties into the duodenum from an inch to an inch and a half below the opening of the common duct. More recently, Hyrtl has called attention to an accessory pancreas consisting of a few isolated acini of the gland behind the superior mesenteric artery and vein. Klob has described an accessory pancreas distinct from the normal organ, which was found between the muscular layers of the stomach, about the middle of the great curvature. On another occasion he found a similar organ in the posterior wall of the jejunum, near its upper termination. In both instances the glandular structure of these bodies was proved by microscopical examinations.

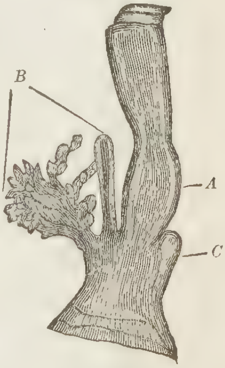
Zenker met with six instances of supernumerary pancreas. The accessory organ was invariably in the walls of the intestine, three times in the highest convolution of the jejunum, twice near the duodenum, and in the last case in the upper portion of the intestinal tract. In size the glands varied from that of a lentil to that of a silver dollar. They were situated between the intestinal tunics, and presented a prominence on the serous surface. Klob found no excretory duct in his specimens. Zenker detected the terminal end upon the mucous surface of the intestinal canal in the shape of a slightly-raised papilla which could be seen with the naked eye or by means of a magnifying-glass. The presence of pancreatic juice in the glands was also determined. In all instances the gland proper was found in its normal location and of natural size. All the patients were adults.

Like other accessory organs, the supernumerary pancreatic glands owe their origin to embryonal deposits of gland-tissue. Although, as yet, no instance has been observed of cystic formation from an accessory pancreas, there is no reason why such an occurrence should not take place, in the same manner as has been observed in cases of cysts from supernumerary thyroid glands, and for the same reasons.

DEVELOPMENT OF THE PANCREAS.

Remak has studied the development of the pancreas in the young chick. He found that the matrix could be seen somewhat later than that of the liver, about sixty-five hours after incubation had commenced. It consists primarily of a bulging of the hypoblast of the posterior wall of the intestinal tube, covered by a thickened prolongation of the connective-tissue layer of the bowel. (Fig. 1.)

Fig. 1.



Embryo of Chick, Four Days old.—*A*, stomach; *B*, liver and bile-ducts; *C*, pancreas.

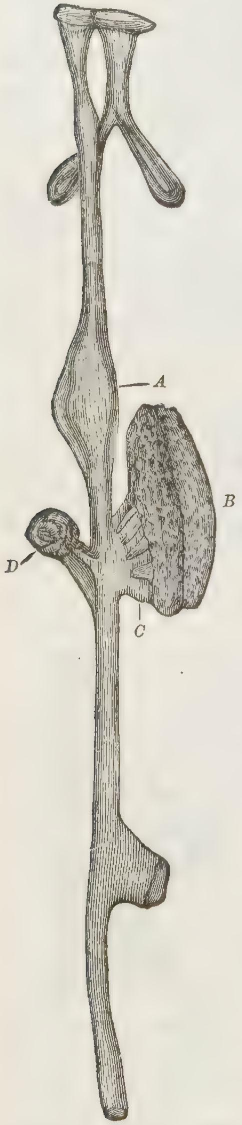
The embryonal pancreas shows in the beginning a cavity which is in communication with the open lumen of the bowel. The changes which take place in the embryonal pancreas during the first five days can be readily observed and are easily understood.

From the thick wall of the hypoblast numerous small, solid lobules spring, while the hollow space in communication with the bowel assumes more and more the shape of a canal. The connective-tissue layer does not increase in size in the same degree, and presents no lobular projections upon its surface. On this account the new organ has assumed a pyriform shape externally; on the other hand, the glandular portion in the connective-tissue layer takes on a branched structure.

The hypoblastic layer is the basis of the parenchyma. Composed of cells, the connective-tissue layer serves as the basis for the vascular constituents of the gland. The embryonal connective tissue disappears during the development of the gland in proportion as the cellular portion increases, until, finally, only enough connective tissue is left to serve as a nidus for the vessels and as a membrana propria of the acini.

The pancreas is not developed by symmetrical folding of both walls of the intestinal canal, but each wall grows by proliferation in different degrees to form the pancreas. The excavation in the rudimentary gland does not exist at first, but the original and essential structures are the cellular parenchyma of the gland from the epithelial lining of the intestine, and the vessel- and nerve-enveloping layer of connective tissue. As the pancreas in birds has two ducts, the question arose how the second duct is formed. The most plausible explanation was afforded by the assumption that the primary duct divides into two in a longitudinal direction. Remak, in 1864, found another explanation by examining two geese, between three and four weeks old. He found two ducts at a short distance from each other in connection with the wall of the intestine. A closer examination showed, however, that only one of the ducts, the upper, was in communication with the lumen of the intestine; the other presented a blind pouch adherent to the wall of the intestine.

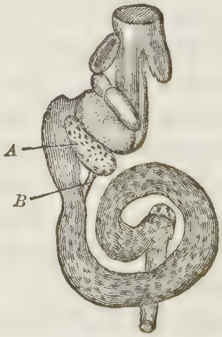
Fig. 2.



Embryo of Chick, Five Days old.—*A*, stomach; *B*, bile-duct; *C*, gall-bladder; *D*, pancreas.

From this it may be concluded that the second duct springs from the first, and that at a later period a new communication with the bowel is established at a point corresponding to its cæcal extremity.

Fig. 3.



Larva of Frog.—*A*, pancreas; *B*, pancreatic duct.

Remak has since observed the same condition in the larvæ of frogs. It appears, then, established that the primary duct of the pancreas is found in the rudimentary organ, and is from the beginning in communication with the bowel, while any additional ducts, whether normal or anomalous, originate in the substance of the gland and only secondarily are brought into communication with the bowel by a process of atrophy and absorption between the cæcal extremity of the duct and the intestinal wall.

The existence of anomalous ducts communicating with one of the principal ducts and the intestine can be explained in a similar manner. Thus, in dogs it is not uncommon to find a small duct in the gastro-splenic half of the gland, connecting the intestine, at a point where the common bile-duct opens into the intestines, with the common duct, as illustrated by a specimen in my possession.

It is apparent that in cases of this kind obliteration of the common duct on the distal side of the anomalous or accessory duct would not interfere with the normal evacuation of the secretion into the intestinal canal. The occurrence of an accessory pancreas can be explained only by the assumption that during the growth of the rudimentary pancreas certain portions of the secreting structure become isolated by constriction and displacement, and that such portions of the gland are brought into communication with the intestinal canal by the development of an accessory duct.

PHYSIOLOGY OF THE PANCREAS.

A brief consideration of the most important functions of the pancreas becomes necessary as an introduction to a study of the diseases and injuries of this organ, as it will serve to furnish an interpretation of some of the symptoms which are observed in the course of affections which interfere with the normal secretion or outflow of the pancreatic juice.

Claude Bernard, in 1848, discovered the most important function of the pancreatic juice, by observing its emulsifying action upon all kinds of fat. He found that by mixing fresh pancreatic juice with oil, lard, butter, or tallow, and keeping the mixture at a temperature of 35° to 40° C., an emulsion is formed almost immediately. Saliva, gastric juice, bile, and blood-serum do not produce this effect. The emulsifying process takes place by the division of the fat into minute globules by the pancreatic juice without its conversion into a new chemical compound. The organic principle in the juice which possesses this property is very easily decomposed and precipitated by heat. Bile with pancreatic juice dissolves neutral as well as acid fats. Bernard ligated both pancreatic ducts in dogs, and the single duct in rabbits, and fed the animals on fat. The fat was found unchanged in the intestinal canal, and the lacteals were empty. Fatty diarrhœa has been observed in a number of cases where the pancreas was the seat of extensive lesions, and the presence of this symptom should always lead the physician to make special search for additional symptoms confirming the suspicion of the existence of disease of the pancreas.

There is no dispute among physiologists in regard to the action of pancreatic juice in transforming starch into sugar. This function was first observed by Valentin, in 1844, who experimented with an artificial fluid made by infusing pieces of pancreas in water. Bouchardat and Sankras first observed this property in the normal pancreatic secretion. The property of converting starch into sugar is possessed also by the saliva and the intestinal juice; it therefore becomes an important question to determine the effect of a defective pancreatic secretion in cases where there is imperfect digestion of starchy food. It seems that cane-sugar is transformed into glucose almost exclusively by the action of the pancreatic juice. This fact has received confirmation in the case of intestinal fistula observed by Busch. The fistula was located in the lower portion of the small intestine. When cane-sugar was introduced in quantity into the stomach, fasting, the fluid which escaped from the upper end of the intestine contained a small quantity of glucose, but never any cane-sugar. Cane-sugar introduced into the fistula so that it would pass along only the lower end of the bowel was not converted into glucose, but a large portion of it was found in the fæces as cane-sugar. In cases of suspected organic lesions of the pancreas it would therefore appear advisable to resort to feeding with cane-sugar and to subsequent examination of the stools for undigested cane-sugar, as a diagnostic measure. The presence of cane-sugar in the stools would indicate that little or no pancreatic juice is secreted.

The last function of the pancreas consists in converting, with the aid of the bile and intestinal juice, the albuminoids, such as gluten, fibrin, albumen, caseine, and musculine, into albuminose or peptones. This latter effect of the pancreas has been doubted by a number of German physiologists, but the fact seems to be demonstrated by experiment as well as by the circumstance that the pancreas is larger in carnivorous than in herbivorous animals.

Schiff has found that the physiological function of the pancreas is at its maximum about nine hours after the ingestion of food, and at its minimum from four to six hours later. During the greatest activity of the gland the vessels become more turgid, and can be seen with the aid of a lens between and upon the lobules, while during a state of rest they are seen only between the lobules. During digestion the gland presents a pale-red color, while during rest it appears grayish white.

The influence of the nerve-centres upon the pancreas has been made a subject of careful study by Schiff. Section of both pneumogastric nerves has no effect upon the circulation or secretion of the pancreas. Animals subjected to this experiment readily digested dextrin or peptones introduced into the stomach; but if ordinary food was given, no secretion took place, as stomach-digestion was suspended. Total destruction of the three semilunar ganglia of the sympathetic arrests completely the secretory functions of the pancreas, even if the most favorable conditions are established by the introduction of food or injection of the products of digestion into the stomach. Wounding of these ganglia, short of total destruction, does not produce the same effect. Injury of the spinal cord on a level with the eighth, ninth, or tenth rib does not interfere in the least with stomach-digestion, but promptly arrests all secretion from the pancreas, which cannot be excited by food nor by the presence of dextrin in the stomach. Heidenhain has ascertained that stimulation of the medulla oblongata increases the flow of pancreatic juice as well as its active constituents. These experiments show that the reflex action of the stomach upon the pancreas is not transmitted through the sympathetic, but through the spinal cord. That the essential active principle of the pancreatic juice is necessary for digestion has been shown by Corvisart, who found that in dogs the pancreatic juice contained, nine and a half hours after a meal, no ferment which was capable of dissolving albuminous substances. If, however, the animal was made to fast for a longer time than this, the ferment was again produced, in some unknown manner. Pancreatic digestion becomes apparent six or seven hours after a meal, the time being somewhat dependent upon the duration of digestion.

The present views concerning the action of the pancreatic juice in the process of digestion may be summarized as follows:

1. Starch is converted by a diastatic ferment into dextrin and sugar, a continuation of the action of the saliva in the intestine.

2. Melted and fluid fats are emulsified by it (a property which has been assigned in a less degree to bile); at the same time, glycerin and fatty acids are formed during the process. The emulsifying process is aided by the fatty acids and alkaline salts which effect saponification. (Brucke, Gad, Quincke.)

3. Albuminous substances and glue-containing tissues when mixed with an alkaline solution are dissolved and converted into peptones, independently of stomach-digestion (Corvisart). A portion of the peptones undergoes still further changes: as, in the case of albuminoid substances, leucin, tyrosin, xanthin, and sarcin, and in the case of glue, tyrosin, glycin, and ammonium, may appear.

Fresh pancreatic juice obtained from the duct of Wirsung is a clear, viscid, alkaline, highly putrescible fluid, of a specific gravity of 1030, which solidifies completely on boiling. Pancreatic juice contains (1) albumen, (2) a number of ferments, (3) salts, especially of soda, (4) water; sometimes traces of self-digestion of the juice can be found, especially leucin. (Hermann.)

The pancreas secretes continually in herbivorous animals; in carnivorous, only during digestion (Heidenhain). The ferments are always present in the gland, trypsin only in a state of preparation, a so-called zymogen, which on division yields trypsin; this division takes place on exposure of the gland to air, to the action of oxygen, of very dilute alkalies, acids, alcohol, etc. During secretion the cells of the lobules are enlarged, while the lobules become swollen; at the same time the vessels are considerably dilated. The exact quantity of pancreatic juice secreted in man and most animals is unknown.

From a practical point of view, it is important to refer to the effect of the pancreatic juice upon the skin, which it macerates, so that when the skin remains in contact with the fluid for any length of time it becomes irritated and presents a raw, eczematous surface. It also appears that the same effect is not produced when the fluid is brought into contact with the peritoneum, because in this locality fresh pancreatic juice is removed rapidly by absorption.

A positive diagnosis of disease of the pancreas will become possible only when more attention shall be bestowed upon the symptoms arising from defective digestion the result of a defective or faulty function of the pancreas,—a pancreatic indigestion. Long-continued indigestion of fatty or starchy food should be considered a sufficient indication for instituting a most careful search for pancreatic disease, by ascertaining the effect upon digestion of particular articles of diet, and by examining with care the discharges from the bowels.

WOUNDS.

Of all abdominal organs the pancreas is most exempt from injury by both direct and indirect violence, a circumstance which is entirely due to its remote location and to the ample protection furnished by the vertebral column and the bony walls of the chest. The anatomical relations of the pancreas to numerous and important organs are such that when this organ is injured the same violence which produced the injury has also wounded an adjacent and perhaps more important viscus. The frequency with which such grave complications accompany wounds of the pancreas and the profuse hemorrhage usually attending such injury are elements of danger which impart to wounds of the pancreas more than an ordinary degree of gravity. Contused wounds of the pancreas, such as are caused by the passage of the wheel of a carriage or wagon over the region of the abdomen corresponding to the location of the pancreas, are attended by such serious injury of one or more of the adjacent organs that in all the cases so far reported death has followed within a few hours. A number of well-authenticated cases are on record where in penetrating wounds of the abdomen the pancreas protruded in part, and the prolapsed portion sloughed or was removed, and yet the patients recovered.

Laborderie reports the case of a girl, aged ten years, who had fallen, while running, upon an open pocket-knife, which inflicted a wound two centimetres below the lower border of the rib, and three finger-breadths to the right of the median line, extending outward for one and a half centimetres, almost horizontal, with a little inclination from above downward. The pancreas was found strangulated in the wound so tightly that not a drop of blood escaped. The author believed that the prolapse was caused by the screaming of the patient. The duct of Wirsung and vessels escaped injury. The abdomen was painless on palpation, and there were no signs of internal hemorrhage. The knife had entered the abdomen under the lobus Spigelii of the liver, and in its course reached the stomach, cut through the gastro-hepatic omentum, and then penetrated between the liver and pylorus to the pancreas, without injuring any of the many large vessels in the locality through which it passed. An attempt to replace the gland was only partially successful. The mass was transfixed and tied at its base with a double ligature, and the portion outside of the ligature removed with the knife. After this procedure nausea and vomiting set in, which, however, soon subsided. The wound was treated by the use of cold-water applications. On the third day the patient complained of being chilly, and the abdomen became somewhat tympanitic and tender on pressure. These symptoms soon subsided, and the ligatures sloughed through, leaving a granulating surface, which healed in fourteen days. Recovery was complete in three weeks.

Hyrtl and Klebs are incredulous as to the prolapse of the pancreas in this case: they believe that the mass which was ligated and removed was not the gland, but a portion of the omentum. Nussbaum, however, in speaking of visceral injuries of the pancreas, states distinctly that in penetrating wounds of the abdomen in the region of the pancreas this organ manifests a tendency to prolapse, and that this circumstance facilitates the treatment, as it protects the peritoneal cavity against infection by plugging the wound, and at the same time affords better access to the bleeding vessels.

In not a single instance of the thirteen cases of injury of the pancreas which the writer has collected did symptoms during life first point to this organ as the seat of lesion. In all cases where the result was fatal, death was not attributable to the visceral lesion of the pancreas, but was always referable to injury of some adjacent organ. With the exception of cases of prolapse of this organ through a penetrating wound of the abdomen, the diagnosis and treatment of injuries of the pancreas will come under the observation of surgeons only in an incidental manner in the treatment of more tangible and graver lesions within the abdominal cavity. Contusion and laceration of the pancreas as independent conditions are not necessarily fatal injuries, and spontaneous recovery may take place, followed by absorption of the crushed portion of the organ and by atrophy of that portion of the gland which has become physiologically detached from the intestinal tract by the injury or its direct consequences. Crushing of the pancreas is usually not attended by hemorrhage, and in laceration of the organ the danger from this source is much less than in cases of incised wounds.

As modern surgery dictates not only the justifiability, but also the absolute necessity, of treating penetrating wounds of the abdomen, where visceral injury is suspected, by abdominal section, the surgery of the future will undoubtedly deal with contusions and lacerations of the pancreas in connection with visceral injury of some of its adjacent organs. If in exploring for injuries in this region the pancreas should be found extensively crushed, it would be good surgery to remove the crushed portion after preliminary ligation of the organ on each side of the comminuted portion. Ligation of the pancreas can be safely done with a single catgut or silk ligature, as the friable texture of the organ will permit of burying the ligature deeply, a circumstance which will guard against the slipping of the ligature. In not a single instance where this method of ligation was resorted to in the experiments on animals was secondary hemorrhage observed from inefficiency of the ligature. If the pancreas is lacerated, each end of the organ should be ligated, for the purpose of arresting or preventing hemorrhage, as well as to guard against extravasation of pancreatic juice into the abdominal cavity.

The results obtained by experiments on animals have demonstrated in a satisfactory manner that normal pancreatic juice when brought in contact with the peritoneum does not produce inflammation, but is promptly removed by absorption. In the experimental work we always had the advantage of dealing with a normal serous surface, the absorption-capacity of which had not been impaired by antecedent pathological conditions, as would in all probability be the case in the operative treatment of injuries of the pancreas. At the same time, there can be no doubt that the presence of crushed pancreatic tissue and pancreatic juice in the peritoneal cavity after abdominal section would greatly enhance the danger of traumatic infection. For this reason, if for no other, the former should be removed, and the escape of the latter prevented by ligation of the pancreas on the side, or on each side, of the crushed or lacerated portion.

The cases of protrusion of the pancreas seem to establish the fact that a portion of this viscus may be separated by violence from the splenic artery and other important attachments, and may prolapse through an external wound, and under such circumstances can be removed without hazardous consequences. In most cases the prolapse followed some time after the injury from a sudden increase of intra-abdominal pressure, as coughing or straining at stool. Klebs and Hyrtl's objection to the possibility of a hernia of the pancreas can find a plausible support only by assuming that the relations of the pancreas have not been disturbed. If by the violence which produced the penetrating wound the attachments of the organ are severed, or in case the attachments have been abnormally loose, or the duodenum is supplied with a long mesentery, there is no tenable reason why the pancreas should not occasionally be found protruding through the external wound. Cases are on record where the pancreas constituted one of the contents of a diaphragmatic hernia, and an instance is reported where it formed a part of the intussusceptum in a case of invagination of the bowel (Bandl).

The treatment of prolapse of the pancreas will depend upon the pathological condition of the viscus at the time the patient comes under the care of the surgeon. If the prolapse is recent, and the organ presents no indication of inflammatory or other changes, it should be thoroughly disinfected and replaced. It is of the greatest importance not to resort to violence in effecting reduction, as irreparable damage may be inflicted by resorting to more than the gentlest force. When reduction is not readily accomplished, the wound should be enlarged. If the pancreas is in a condition of inflammation or gangrene, the parts should be thoroughly disinfected and the organ pulled farther into the wound until healthy tissue is reached, when a ligature is applied and the diseased portion removed with the knife or scissors. After another thorough disinfection the stump is dropped into the abdominal cavity and the external wound closed. Thorough primary removal of infected tissue is the only safety against subsequent extension of the infection to the peritoneal cavity, and the only guarantee for primary union of the abdominal wound.

In gunshot wounds of the pancreas we have no guiding symptoms upon which to base even a probable diagnosis. The wounds of entrance and exit of the ball, and its probable course, are the only facts which may point to the pancreas as one of the injured organs. In four out of five cases of gunshot wound of the pancreas the projectile penetrated posteriorly in the space between the angle of the left scapula and the angles of the ribs, and passed through the diaphragm and the solar plexus; in one the ball entered anteriorly near the tip of the xiphoid cartilage, and was believed to have passed through the stomach.

It is a somewhat significant fact that in all cases where life was prolonged for more than twelve days, the pancreas appeared to have undergone little or no pathological change in the vicinity of the visceral wound. Although the track of the ball did not in all cases remain aseptic, the inflammatory changes did not materially affect the parenchyma of the gland.

In a case of gunshot wound of the pancreas reported in the "Medical and Surgical History of the War of the Rebellion," Part II. vol. ii., the patient recovered from the immediate effects of the injury, death occurring from other causes a few weeks later. The post-mortem showed that the formation of a capsule around the bullet had already been initiated, and there is every reason to believe that if the patient had lived the foreign body would have become encysted in the parenchyma of the pancreas. Gunshot injuries of the pancreas, where they come under the observation of the surgeon as independent lesions, or as complications of other visceral injuries in cases of penetrating wounds of the abdomen treated by laparotomy, should be treated in the same way as a contusion or a laceration of the gland. The results obtained by the experiments have shown that if only a comparatively small portion of the pancreas remains in physiological connection with the duodenum, this portion of the gland retains its normal structure and its physiological function; and in all the experimental cases this was found adequate to supply the quantity of pancreatic juice necessary for the maintenance of normal digestion. While the surgeon may unhesitatingly remove the tail and a portion of the body of the pancreas without fear of any ill effects, either immediate or remote, great care must be exercised in operating in the vicinity of the head of the pancreas, to preserve the integrity of the common duct and as much of this portion of the organ as may appear compatible with the condition which necessitated the operation.

The results of my experiments, made with a view to ascertain how much of the mesentery of the duodenum can be detached without causing gangrene of the bowel, have been such as to encourage a conservative plan of treatment when operating in close proximity to the intestine. The observations made in this direction have shown that it is comparatively safe to detach a portion of the mesentery to the extent even of one to three inches, a procedure incomparably easier and much safer than enterectomy combined with partial excision of the head of the pancreas. I wish again to emphasize the fact that complete extirpation of the head of the pancreas with the common duct is never justifiable, and that operations upon this portion of the gland for injury or disease must be limited to partial excision of the head, with preservation of the common duct.

ACUTE PANCREATITIS.

Acute idiopathic pancreatitis is an exceedingly rare affection: only a few well-authenticated cases of this disease have been reported, and none of the patients were children. The comparative immunity of the pancreas from disease is attributed by Gross to the singular structure of this organ, to its concealed situation, and to the absence of everything like a proper envelope. A brief consideration of this affection is necessary for the purpose of calling attention to a few of the most constant and prominent symptoms which characterize the disease, inasmuch as all suppurative lesions of the pancreas are preceded by acute or subacute inflammation. The disease either originates primarily in the inter-acinous connective tissue of the organ as a pancreatitis, or occurs as a secondary disease from an extension of a peri-pancreatitis to the substance of the gland.

Haller and Klob have given an accurate clinical description of a case observed at the Allgemeine Krankenhaus in Vienna, with a careful account of the post-mortem appearances. In one of the reported cases the symptoms were acute, and the disease terminated in death in the short space of sixteen days. The suppurative inflammation, beginning in the interstitial tissue, involved the entire gland, and extended by continuity to the para-pancreatic and peri-pancreatic tissue, giving rise to a diffuse and acute abscess. The termination in this case is sufficient evidence that the inflammation was produced by a specific cause,—infection with pus-microbes. In another case the primary seat of the inflammation was the same, but the process assumed a subacute course and terminated in a hyperplasia of the connective tissue. The most prominent symptoms in all the cases thus far reported were severe pain in the epigastrium, progressive anæmia, and obstinate vomiting. The pain was intermittent and neuralgic in character, and was referred to the region of the cœliac plexus, radiating from there over the abdomen. Neuralgia of the cœliac plexus is one of the most constant symptoms of disease of the pancreas: Klebs alludes to it as being present eleven times in fifteen uncomplicated cases. Atrophy of the cœliac plexus is mentioned by the same author as the cause of the neuralgia. All the patients suffering from acute pancreatitis presented an extremely anæmic appearance, and it is stated that one of them resembled a person who had suffered from repeated and severe hemorrhages. As the pancreas is not concerned directly in the function of hæmatogenesis, we can explain the constancy with which this symptom is present only by assuming that the anæmia was due to impaired digestion and assimilation, caused by arrest of the physiological function in the inflamed organ. In the reported cases no mention is made of the character of the stools. The presence of undigested fat in the stools is, however, one of the rare symptoms of other affections of the pancreas, and consequently it must be present at least in some of the cases of acute inflammation of this organ when the secretion of the pancreatic juice is arrested by the inflammatory process. Klebs states that in three cases where this symptom was present the duct of Wirsung was either entirely or partially obliterated, while in a number of cases where the duct was in the same condition the stools remained normal.

Acute parenchymatous pancreatitis is frequently met with in children as a complication in cases of typhoid fever, pyæmia, septicæmia, yellow fever, and other acute infectious diseases. In this form of pancreatitis the organ appears red, swollen, and œdematous. Microscopically the most prominent lesion consists in swelling and undue granulation of the parenchyma-cells and in hyperæmia.

In non-suppurative pancreatitis the treatment should be commenced by the administration of small and frequently-repeated doses of calomel, followed by a saline cathartic, for the purpose of diminishing the hyperæmia and limiting the inflammatory exudation. Hot fomentations over the epigastric region will relieve the intensity of the pain, and at the same time will influence favorably the absorption of the inflammatory product. The diet must be carefully regulated and only such food allowed as can be digested and absorbed without the action of pancreatic juice. The employment of artificial digestive ferments with the food, such as pancreatine and extractum pancreatis, should be continued until the function of the gland has been restored. If the general and local symptoms point to suppuration within or around the organ, the same prompt surgical measures must be adopted as are described under treatment of pancreatic abscess.

CHRONIC INTERSTITIAL PANCREATITIS, OR SCLEROSIS OF THE PANCREAS.

This lesion consists in an increase of interstitial connective tissue, which may affect the entire organ or remain limited to some particular portion, more especially the head of the gland. During the early stages of the disease the organ is enlarged, more vascular, and firm, while later the cicatricial contraction of the interstitial deposit produces atrophy of the parenchyma, with a corresponding diminution in the size of the organ. This form of inflammation of the pancreas is of particular interest to the surgeon, as the cicatricial contraction may produce secondary changes in the pancreatic duct or bile-ducts, an occurrence which would indicate a resort to surgical measures for the relief of immediate symptoms due to retention of the secretions.

The causes which produce sclerosis are often obscure, but usually are referable to some antecedent affection in some of the organs adjacent to the pancreas, as the peritoneum, subperitoneal tissue, duodenum, or common bile-duct, or to pancreatic lithiasis, in which case the primary cause is in the pancreas itself. The connective-tissue proliferation destroys the parenchyma by compression and constitutes one of the causes of stenosis of the pancreatic duct.

Todd observed this condition in a girl fourteen years of age, in whom the disease was situated in the head of the pancreas and the neighboring connective tissue. This case is of unusual interest, as the contraction of the cicatricial tissue produced obstruction of the common bile-duct by compression, which caused a dilatation of the bile-ducts behind the seat of obstruction, converting them into a large sac, which was located behind the duodenum and reached downward as far as the sacrum and laterally from one kidney to the other.

The medical treatment of chronic interstitial pancreatitis must be purely symptomatic. Indications must be met as they appear, and the diet selected with a view of taxing pancreatic digestion as little as possible.

The surgical treatment of sclerosis of the pancreas can apply only to secondary lesions which result from stenosis of the pancreatic duct or bile-ducts and to distention of these passages by accumulation of the secretions. Such an occurrence is most apt to take place when the disease affects the head of the pancreas, as the cicatricial contraction in this locality may cause stenosis of either the duct of Wirsung or the common bile-duct, or of both. Any operative interference in these cases will of necessity be limited to an attempt to secure an artificial outlet to the retained secretion. The restoration of the permeability of the natural outlet by any method of treatment is entirely out of the question.

The tendency of the disease is to aggravate the obstruction as cicatricial contraction progresses. The history of all these cases pointed to an impairment of digestion as the principal clinical feature in each instance. It is, therefore, of considerable importance to examine carefully into every obstinate and obscure case of indigestion, with a view to eliminate the possibility of organic disease of the pancreas as the cause of the derangement of digestion. In cases of permanent retention of the bile or the pancreatic juice caused by cicatricial compression of the bile-duct or the pancreatic duct, the earlier symptoms will have reference to a history of obstinate indigestion progressive in its character. If, on the other hand, the obstruction is produced by the impaction of a calculus, the previous history points to attacks of sudden and severe pain and other symptoms indicative of the passage of a calculus along the excretory duct.

In a case of biliary retention-cyst like that cited above, the establishment of an external biliary fistula would result in a permanent fistula, as the impermeability of the bile-duct would preclude the possibility of re-establishing the normal communication between the dilated bile-passages and the intestine. Such an operation would remove only the urgent symptoms due to retention and absorption of bile, but would leave unchanged the primary cause of the retention and would permanently exclude the bile as a digestive fluid from the alimentary canal. As the obstruction is permanent and irremediable, the operation which suggests itself as fulfilling the urgent indications, as well as preventing remote ill consequences, is the formation of a new outlet for the bile into the intestinal canal, by establishing a permanent fistula between the duodenum and the gall-bladder, or between the duodenum and the dilated bile-ducts. Duodeno-cholecystotomy has a future in all cases of permanent and incurable obstructive lesions in the bile-duct, and will become an established operation as soon as it has been perfected by an improved technique.

My experiments on animals have demonstrated that physiological detachment of any portion of the pancreas is invariably followed by degeneration and atrophy, irrespective of the particular method by which this detachment is effected; consequently, it is only reasonable to assume that permanent obliteration of the pancreatic duct by cicatricial contraction is always followed by degeneration of the parenchyma of the gland on the distal side of the seat of obstruction.

It is on this account that stenosis of the pancreatic duct is seldom followed by dilatation of the ducts to any considerable extent on the distal side of the constriction, and even more seldom by the formation of a cyst. A retention-cyst can result from obstruction only so long as secretion has not been entirely suspended, and when at the same time absorption of the pancreatic juice does not take place on account of further extensive pathological changes in the structures which perform this function when the gland is otherwise in a normal condition.

As the physiological detachment by obstruction of the common pancreatic duct caused by cicatricial contraction is invariably followed by complete destruction of the parenchyma of the contributory portion of the gland, it is evident that the surgical treatment of a cyst of the pancreas in such cases can be indicated only when the swelling becomes in itself a source of serious inconvenience and pain. The proper treatment in all such cases consists in the formation of an external pancreatic fistula by abdominal section. There is no danger, in such instances, of the fistula remaining permanent, as the glandular tissue which might remain at the time of operation will, in the course of time, disappear by degeneration and absorption. As in animals, so in man, the health of the individual after gradual atrophy of the pancreas will depend upon the physiological capacity of vicarious organs, in each particular case, to assume the functions of the pancreas.

In recapitulation, it may be stated that cirrhosis or chronic interstitial pancreatitis sometimes produces stenosis of the bile-duct or of the pancreatic duct, and that when the obstruction is followed by retention of the secretions an operation becomes always necessary in biliary retention, which should be treated by establishing a new outlet for the bile into the duodenum, while the formation of an external pancreatic fistula in cases of cyst of the pancreas becomes necessary only when the presence of the swelling in itself has become a source of sufficient pain and discomfort to warrant treatment by abdominal section.

GANGRENE OF THE PANCREAS.

One of the terminations of acute inflammation of the pancreas is gangrene. Cases have been reported where spontaneous recovery followed elimination of the necrosed organ through the alimentary canal. If spontaneous recovery in this condition is possible, it would seem plausible that a timely removal of the necrosed organ by surgical interference would add to the chances of recovery; consequently we include gangrene among the diseases of the pancreas which should be treated by operative measures.

The pancreas may constitute one of the component parts of the intussusceptum in cases of invagination of the bowels. Such a case has been reported by Bandl, and the specimen examined by Rokitansky furnishes a similar illustration. A case reported by Chiari may have been of a similar nature, the invaginated portion having sloughed with the remaining portion of the intussusceptum, leaving the continuity of the bowel unimpaired by adhesions at the point of separation. If in this instance the necrosis was due to inflammation, we can only infer that the para-pancreatic abscess ruptured into the bowel, that the necrosed portion of the pancreas was eliminated in this manner, and that subsequently the opening in the bowel was closed. Constipation was a prominent symptom in a number of these cases, and in Rosenbach's case the symptoms of obstruction were so well marked that it was decided to perform laparotomy for its relief. This last case is also of great interest, as during life the existence of a tumor in the region of the pancreas was diagnosticated.

Modern surgery deals extensively with abdominal section for the relief and cure of peritonitis and intestinal obstruction. In searching for the cause of either of these conditions during laparotomy, the pancreas should not be forgotten, and when it is found that the primary disease is located in or around this organ, radical measures should be adopted whenever they are practicable.

Whenever the sac can be stitched to the external incision this should be done, and the sac opened, disinfected, and drained. Search should be made for the necrosed pancreas, and when found detached it should be removed. As in most of these cases the retro-peritoneal tissue is extensively infiltrated, a counter-opening should be made in the lumbar region above the kidney, and through drainage established. If an anterior abdominal fistula cannot be established, the course to be pursued should be the same as in treating a pancreatic abscess under similar conditions.

ABSCESS OF THE PANCREAS.

At the present time no one familiar with the recent advances in surgery would question the propriety of treating a suppurating cavity by incision and drainage, wherever it might be located. Some of the most valuable recent contributions to surgical literature describe improved methods in treating deep-seated abscess. Asepsis and effective drainage are the two cardinal points upon which we have learned to depend in the treatment of abscesses in important organs or cavities. If we can secure and maintain these two essential conditions, we can attack with immunity, and a fair hope of success, any abscess, wherever it may be located, and whatever its immediate surroundings may be.

In looking over the literature on abscesses of the abdominal organs, we find that modern surgery has been guided almost exclusively by the teaching of the old master: *Ubi pus, ibi evacuo.* It is somewhat surprising that abscess of the pancreas has never been made the subject of surgical treatment. The two principal reasons for this may be found in the facts that abscess of the pancreas is of rare occurrence, and that the recognition of the lesion, when it does exist, is surrounded by many difficulties. There can be no doubt, however, that in the near future abscess of the pancreas will be treated on the same principles as suppuration in any other locality.

The remote location of the abscess may offer many serious obstacles to diagnosis and a rational course of treatment, but these difficulties will be overcome by improved methods of examination and more perfect methods of operation. As suppuration is only one of the terminations of inflammation, abscess, like inflammation, may occur primarily in the gland itself, or it may commence in the para- or peri-pancreatic tissue. If the abscess is endo-pancreatic, it may be bounded and circumscribed by the proper investment of the gland; if, on the other hand, it commences primarily outside of the gland, it appears as a diffuse abscess, which extends to the pancreas by contiguity; in other words, we speak of the abscess as a suppurative pancreatitis, or a suppurative peri- or para-pancreatitis.

Pathology of Abscess of the Pancreas.—Recent investigations have shown the existence of a direct causative relation between the pus-microbes and suppuration: hence we must take it for granted that every purulent pancreatitis, peri-pancreatitis, or para-pancreatitis is caused by the presence of these germs in the tissues. In case there is no direct invasion by a loss of continuity of the hollow viscera in the vicinity of the pancreas, or no direct communication with the external air by a penetrating wound, we must assume that the germs reach the gland through the circulation and find a favorable soil prepared by some antecedent pathological change. Such conditions may be determined by contusion of the organ, disturbance of the capillary circulation by various causes, or thrombo-phlebitis. Norman Moore reports the case of a female, twenty-seven years of age, who died of pyo-phlebitis, and in whom, on post-mortem examination, besides the portal, splenic, and vena azygos minor veins, the pancreatic veins were blocked by decolorized and adherent thrombi.

In the "Pathological Society's Transactions" the same author gives an account of two cases of abscess of the pancreas due to plugging of the pancreatic vessels. On page 210 he remarks, "Pathologically, the case in which thrombosis of the pancreas was found is interesting as indicating how pancreatic abscess is produced. The much commoner condition of the liver in the other cases shows that, had the first patient survived, the thrombosis would certainly have been followed by abscess. Clinically, the value of the case is that it may, in rare cases, help to explain the seat of an obscure abdominal swelling, associated with fever, which has followed a thrombosis, and which physical examination cannot localize in the liver."

Suppuration always begins in the interstitial tissue, either within the gland or in the connective tissue around it. A suppurative inflammation and formation of an abscess are different stages of the same process. Peripancreatic suppuration commences, in most instances, in the adjacent lymphatics, the pus surrounding the lymph-glands or forming a small abscess.

In the vicinity of the pancreas these peri-lymphatic abscesses are not unfrequently met with as one of the pathological conditions of pyæmia. Thus, an abscess in the pancreas with perforation into the peritoneal cavity was examined by Perle. Tulpius saw an abscess of the pancreas as a secondary lesion after an attack of malarial fever. Schmackpfeffer observed the same condition after an operation for strangulated hernia, and Portal after extirpation of a testicle. But suppuration in the pancreas sometimes takes place as an independent affection, without the presence of an appreciable infection-atrium, and in these cases we must assume that the essential and specific noxæ are carried along with the circulating blood, and that localization takes place upon a soil prepared for their reception and growth by previous alteration in texture or circulation. In some instances the process begins upon the outer surface of the gland, the pus separating the gland from its attachments. In the case described by Gendrin the pancreas appeared to have been completely detached, and was lying loose in the abscess-cavity.

Many of these para-pancreatic abscesses do not present well-defined borders; the pus manifests a tendency to burrow in the vicinity of the mesocolon and the retro-peritoneal space, and is apt to perforate into the bursa omentalis, or into some other portion of the peritoneal cavity, or, lastly, finds its way into one of the adjacent hollow organs, as the stomach or the intestinal tract.

Van Derveren reports the case of a female who had suffered for thirty years from attacks of gastralgia. At the necropsy it was ascertained that the indurated pancreas had perforated the posterior wall of the stomach. The opening represented a round ulcer, two and a half inches in diameter, with indurated margins. In this aperture eroded vessels could be seen. The fistulous tract communicated with the pancreatic duct. The stomach and intestines contained blood, but no other evidences of disease could be found. In Percival's case the abscess ruptured into the bowel, the stools containing fetid pus and blood. A similar case was observed by Haggarth.

The suppurative process, however, may extend in an opposite direction, from the stomach to the pancreas. A communication between the stomach and the pancreas is sometimes established by perforation of a gastric ulcer in this direction. Around the margins of the ulcer, between the stomach and the pancreas, adhesions are formed, an occurrence which prevents extravasation of the contents of the stomach into the peritoneal cavity. A number of the terminal openings of the pancreatic ducts have been observed upon the cicatrized surface of a gastric ulcer. In place of the formation of a permanent pancreatico-gastric fistula as described by Rokitansky, perforation of the stomach in closer proximity to the pancreas may give rise to diffuse and rapidly-fatal para-pancreatitis or peri-pancreatitis.

The indirect primary cause of a pancreatic abscess may be the presence of a calculus in the pancreatic duct. Fournier has recorded a case where, on post-mortem examination, an enormous abscess was found in the head of the pancreas, which contained numerous calculi. The tumor was sufficiently large to be readily detected in the epigastric region during life.

An abscess of the pancreas may also originate in a pre-existing cyst of the organ. Kilgour's case had undoubtedly such an origin. The abscess-cavity was as large as a teacup, and contained a milky fluid and caseous particles, which were undoubtedly a mixture of pus and pancreatic juice. The disease was attended by chills and fever, which indicated that the retention-cyst had become the seat of an acute suppurative inflammation.

As primary, idiopathic, uncomplicated, purulent inflammation of the pancreas is an exceedingly rare affection, it is of great practical importance in the surgical treatment of such cases to determine, if possible, the predisposing cause or causes, and to remove them, or render them inert, at the time of operation.

Symptoms and Diagnosis.—The presence of pus within the pancreas or in its immediate vicinity is not indicated by any characteristic or positive symptoms. The symptoms always point to the stomach or liver as the seat of the disease. The most prominent and constant symptoms which have been observed are nausea, vomiting of a clear greenish or viscid fluid, thirst, loss of appetite, constipation, progressive emaciation, and distention of the epigastrium.

In almost all cases the patients presented a sallow, cachectic appearance, and were exceedingly anæmic. Ascites and œdema of the lower extremities were present a number of times. In several instances the inflammatory process in the pancreas extended to the bile-duct, or caused stenosis of the duct by compression, conditions which are followed by biliary retention, a symptom which has usually been interpreted as an evidence of primary disease of the liver or bile-ducts. The progressive anæmia and emaciation, in the absence of other tangible lesions, are symptoms which always should direct attention to the pancreas as the seat of the disease.

Fever was seldom a conspicuous and never a constant symptom of suppurative pancreatitis. The use of the thermometer in the diagnosis of suppuration in this locality is important, but it furnishes no positive evidence. If the abscess is large, it will be recognized by palpation and deep percussion as a tumor in the epigastric region. In such cases a probable diagnosis may be made by a careful and systematic physical examination and reasoning by exclusion.

An abscess within the gland is always located in the bursa omentalis; a peri-pancreatic abscess, in the bursa omentalis, duodeno-jejunal fossa, or upper portion of the peritoneal cavity; and a para-pancreatic abscess, in the retro-peritoneal space. Inflammation of the stomach will often serve a useful purpose in the differential diagnosis of tumors in the epigastric region. In obscure cases, manual exploration of the rectum may add important and sometimes decisive information.

Age is also an important element to be considered in the diagnosis. Most of the cases of abscess of the pancreas were patients over forty years of age, and often persons of intemperate habits. Puncture with an aseptic capillary needle will demonstrate the presence or the absence of pus, but will not add material information in locating with accuracy the abscess-cavity.

Finally, in all cases where a tumor can be felt in the epigastric region, and a probable diagnosis can be made regarding its benign character, an exploratory laparotomy should be resorted to for the purpose of making an accurate anatomical diagnosis.

Prognosis.—The prognosis of abscess of the pancreas is always unfavorable. Death is produced by progressive emaciation and inanition, by septic absorption, or by secondary lesions in adjacent organs. In acute diffuse pancreatic abscess a fatal termination may take place in a few days. One of the great dangers of abscess in this locality is the close proximity of numerous important veins, which become implicated by extension of the suppurative inflammation to their walls, producing a suppurative thrombophlebitis, with all its disastrous consequences. Perforation of the abscess into the stomach or the intestinal tract is the most favorable spontaneous termination, and has resulted at least in one instance in a cure. Perforation of the abscess into the peritoneal cavity would hasten death by inducing a rapidly-fatal septic peritonitis.

Treatment.—The remarkable success which has attended the treatment of pelvic and abdominal abscesses by laparotomy justifies the hope that in the near future the same treatment will be extended to abscess of the pancreas. It is true that the difficulties which surround the treatment of abscesses in this region are many, but they are not insurmountable. Multiple abscesses disseminated through the entire organ, and especially in its head, are not amenable to successful surgical treatment. Circumscribed endopancreatic abscess in the peripheral portion of the body or tail of the pancreas should be treated by partial excision of the pancreas in all cases where the isolation of that portion of the organ can be accomplished without inflicting serious injury upon adjacent important organs. When extirpation is impossible, as when the abscess is located in the head of the pancreas, it must be treated by incision and drainage. This is accomplished in the same manner as in the treatment of a pancreatic cyst. In some instances the access to the abscess is rendered difficult by distention of the stomach, the dilated organ overlapping the pancreas. In such cases the stomach must be pushed upward, and subsequent distention guarded against by ordering an absolute diet until the external fistula has been established. The external incision must in all cases correspond to the most prominent part of the swelling, as it is of the greatest importance to incise the abscess at a point where the distance between the surface of the abscess and the abdominal wall is the shortest. Incision of the great omentum will be required in all instances.

In making an external fistula in the treatment of a pancreatic abscess it is essential to protect the muscular and connective tissues of the external incision against contact with pus by lining the margins of the wound with the parietal peritoneum before the serous covering of the anterior wall of the abscess is stitched to the margins of the wound. One of the greatest difficulties that will be encountered in this operation will be the approximation of the peritoneal surface of the abscess with the margins of the wound, on account of the distance between the surface of the abscess and the anterior abdominal wall: this difficulty will decrease in proportion to the prominence of the swelling.

The size of the external incision will exert an important influence in this direction. If the incision is large, the margins of the wound can be turned inward, thus facilitating the suturing of the anterior wall of the abscess to the margins of the wound. As a rule, it may be relied upon that the anterior wall of the abscess, covered by peritoneum, is quite thick, so that there is little danger of penetrating the abscess-cavity with the needle in suturing. Previous evacuation of the abscess-cavity by aspiration would diminish the danger of extravasation of pus through the needle-punctures, but would also render approximation difficult by the recession of the abscess-wall, and should, therefore, not be resorted to unless the swelling is sufficiently prominent to render this circumstance of little importance.

As the suturing of the two peritoneal surfaces is done for the purpose, in the first place, of preventing extravasation of pus into the peritoneal cavity, and, secondly, of securing permanent adhesions between the abscess-wall and the margins of the wound, it is important to apply the sutures closely together and to grasp the tissues in such a manner that tearing through of the sutures is impossible. As considerable tension may follow, it would be advisable, in this particular instance, to use silk sutures. As in these cases time is an important element, incision and drainage should follow suturing immediately.

The remaining steps of the operation will depend upon circumstances. If the abscess is endo-pancreatic or peri-pancreatic, simple incision, drainage, and disinfection will answer all indications. If, however, the purulent cavity is located behind the peritoneum and occupies the connective-tissue space behind the pancreas, it would appear rational to drain the abscess posteriorly through one of the lumbar regions above the kidney by pushing a long closed forceps in a proper direction through the posterior and lateral wall of the abscess until its point can be felt under the skin externally. A small cut in the skin over its point will enable the operator to push the instrument clear through, and, by dilating its blades, widen the canal sufficiently to permit the insertion of a large drainage-tube. In this manner the most desirable method of drainage—through drainage—could be established, which would render subsequent disinfection and evacuation of the abscess a comparatively easy task. In cases where an anterior pancreatic fistula cannot be established, on account of the distance between the abscess and the anterior abdominal wall, we might resort to lumbar drainage, and closure of the incision in the anterior wall of the abscess by carefully inverting and approximating the peritoneum over the wound with fine silk sutures.

That the utmost care in the application of antiseptic precautions should be resorted to in the evacuation of pus in this remote region by any of these procedures requires no argument. I will repeat that a positive diagnosis of the presence and precise location of a pancreatic abscess is possible only by resorting to explorative laparotomy, and that this diagnosticial aid should always be resorted to when the history of the case and the symptoms and signs presented are sufficiently suggestive to point to a probable diagnosis.

The abscess found and located by abdominal section should be removed by partial extirpation of the pancreas when it is endo-pancreatic and located near the splenic end of the pancreas. When extirpation is impossible, or when the abscess is located in the head or on the anterior surface of the pancreas, it should be treated by the formation of an anterior abdominal fistula; when located behind the pancreas, by through drainage, or by lumbar drainage performed through the abdominal cavity.

CYSTS OF THE PANCREAS.

During the last few years eighteen cases of cyst of the pancreas have been reported, and, as most of the patients recovered under proper surgical treatment, the treatment of such cases by abdominal section has become an established operation. The youngest of the patients so far reported was a girl sixteen years of age, but there is no reason why this affection should not occasionally develop during childhood as the result of injury, or following in the course of lesions in the pancreas which cause obstruction and at the same time suspend auto-absorption of the retained secretion.

In my experiments upon the pancreas in animals it became apparent that simple obstruction never causes the formation of a cyst, but that the most important factor which determines cystic disease in the pancreas is an alteration of its tissues which suspends the absorption of pancreatic juice behind the seat of obstruction.

The case referred to is reported by Kramer; the operation was performed by Hahn. Female, sixteen years of age, after an attack of vomiting and pain in the abdomen, noticed a gradual distention of the upper portion of the abdominal cavity. The size of the tumor and area of dulness corresponding were about the same as in my case. The dulness appeared to be continuous with the hepatic dulness. Echinococcus cyst of the liver was diagnosticated. Laparotomy was performed, and the omentum divided between the stomach and the transverse colon. About two litres of an albuminous fluid were removed by tapping. The cyst was stitched to the margin of the abdominal wound, incised, and drained. The patient recovered, with an external pancreatic fistula, which continued to secrete pancreatic juice for four months.

Etiology.—The causes which result in the formation of small cysts of the pancreas, or cysts which result from compression by tumors, which in themselves do not admit of an operation for their removal, and at the same time constitute a source of danger to life, do not come within the scope of this paper. In the latter instance the cyst is simply a sequence of the primary cause, and as such it will seldom, if ever, become the sole or direct object of surgical treatment. The causes of retention-cysts amenable to operative treatment are such as do not in themselves imperil the life of the patient. They may be classified as follows: 1. Obstruction to the outflow of the secretion from impaction of calculi in the common duct or its branches. 2. Partial or complete obliteration of a portion of the duct from cicatricial contraction. 3. Sudden or gradual obstruction of the duct, without diminution of its lumen, from displacements of the pancreas.

1. *Calculi.*—The impaction of the pancreatic duct at its outlet may be caused by the presence of a biliary calculus in the ductus communis choledochus, at the junction of the former with the latter. A case of this kind has been reported by Engel. In such cases the obstruction gives rise to retention of the secretions from the liver and the pancreas, and dilatation of the excretory ducts in both organs. Calculous concretions in the pancreatic ducts have been frequently observed to give rise to retention-cysts. Johnston has collected thirty-five cases in which, upon post-mortem examination, stony concretions were found in the pancreas. Incrustations are not so frequent as free concretions. Gendrin has described a pancreatic cyst where the normal pancreatic secretion was converted into a fatty, chalky pap. The causes which produce a concretion in the pancreatic duct are chemical changes in the secretion itself, or an obstruction to its free exit by inflammatory changes in or around the common duct. The degree of dilatation, other things being equal, is in direct proportion to the completeness of the obstruction to the outflow of the secretion. It may be well to allude to the possibility that in some instances a pancreatic calculus may remain stationary for an indefinite period of time in the duct, giving rise to no symptoms and causing only partial obstruction, until, by the action of some determining cause, it is forced into a position where it effects complete mechanical obstruction to the outflow of the fluid, and a rapid increase in the size of the cyst. As an impacted biliary calculus may give rise to pancreatic obstruction, so a pancreatic calculus, when it is impacted at a point where compression of the common bile-duct can take place, will produce icterus and dilatation of the gall-bladder and bile-ducts. Meckel has reported such a case.

Among the specimens of pancreatic cysts so far examined which were caused by concretions, none had attained the size of those which have been submitted to surgical treatment. As in most of these preparations the calculi did not completely fill the calibre of the duct, they caused only partial obstruction, which would furnish an explanation of the slow growth and comparatively small size of the tumor. In the specimen described by Gould it appears that the common duct was completely closed by two calculous concretions at its entrance into a chalky deposit four to eight inches in length and of a yellowish color. The duct of Wirsung was dilated to such an extent as to form a large cyst, which occupied the whole length of the pancreas, its walls being inseparable from the substance of the gland. In this case the interstitial inflammation was more extensive and the cyst was much larger. In the cases reported by Pepper and Hjett the obstruction was due to the same cause. In Curnow's case the common duct had become obliterated at its entrance into the duodenum by catarrhal inflammation. The pancreas was atrophic, and its duct was filled with numerous calculi. The pancreatic juice had become inspissated. The cystic duct of the gall-bladder was impermeable, while in the common bile-duct a number of small gall-stones were found.

2. *Cicatricial Contraction.*—I have failed to find in the literature any allusion to stricture of the duct, resulting from traumatism. In the case that came under my own observation the patient was nineteen years of age, and the cause was clearly traceable to an injury which he had sustained a few weeks before the cyst became apparent in the epigastric region.

The pancreas is an exceedingly slender organ, of loose and somewhat friable texture, and hence, although remotely located and well protected by surrounding organs, I am of the opinion that it is the seat of injury more frequently than has been generally supposed. If the stomach is empty and the abdominal muscles relaxed, a blow over the region of the pancreas may result in serious contusion or laceration of the organ without rupture of its envelope. Again, a well-directed blow over either extremity of the gland may cause a laceration of its tissues by traction, the organ being securely fixed in its place by firm connective-tissue attachments. The clinical history of several cases of rapidly-growing cysts tends to prove that obstruction occurred in this manner. If the duct escapes injury, the cicatricial contraction attending and following the reparative process in the lacerated gland-tissue will gradually compress the duct, or by lateral traction change its direction and thus impede the outflow of the secretion. If the duct is ruptured at the time of injury, its lumen may become completely filled by a thrombus which renders it impermeable, giving rise to retention and extravasation of the secretion primarily, and secondarily to definitive occlusion of the duct by cicatricial contraction at the point of injury. I am quite convinced that in the case which I have reported the retention was the direct result of traumatic stricture of the common duct. Although this view is not supported by evidence from post-mortem examinations, it is confirmed by analogous production of cysts in other locations. It is evident that this class of cases would furnish the most favorable conditions for successful surgical treatment.

3. *Obstruction from Displacement of the Pancreas.*—As the pancreas is retained in its normal transverse position by the surrounding organs and connective-tissue attachments, a relative change of position of portions of the gland would result in a bending of the organ and obstruction in the duct at the point of flexion. This condition was the cause of retention in a case related by Engel, who in a woman sixty years of age found that the tail of the pancreas formed with the principal duct of the gland a right angle upward. A dislocation of this kind can occur in one of the following ways:

1. Through abnormal relaxation of the connective-tissue attachments of the gland, permitting a portion of the organ to descend by its own weight lower in the abdominal cavity.
2. From pressure upon the gland by tumors or exudations.
3. From cicatricial contractions in the substance of the organ or in the peri-pancreatic space.

That the whole pancreas can become displaced is proved by the case reported by Dobrzycki. A man fifty years of age fell a distance of some yards; after the fall symptoms arose similar to those of a floating kidney. By palpation the displaced organ could be located. Saline fluid resembling pancreatic juice was vomited. In the hypogastrium a movable tumor corresponding in position and shape to the pancreas could be felt.

Diagnosis.—The question of diagnosis can be entertained only in cases where the cyst has attained very considerable proportions. The most important points to be taken into consideration are the history of the case, the anatomical location of the tumor, and its relations to the surrounding organs. The cases which have been reported have occurred exclusively in adults. Sex appears to exert no determining influence. In a number of cases the clinical history refers distinctly and forcibly to traumatism as the exciting cause. In Gussenbauer's case the beginning of the illness was traced to indiscreet eating and drinking.

In all instances of cystic tumors in the region of the pancreas, close inquiry should be made to ascertain the existence of antecedent inflammatory affections of the organ or in its immediate vicinity. A history pointing towards the existence of a biliary or a pancreatic calculus will also prove valuable in arriving at positive conclusions. Rapid growth of the tumor speaks in favor of its pancreatic origin. In Gussenbauer's, Kulenkampff's, and my own cases the tumor attained an enormous size within a few weeks. Considering the relations of these cysts to important surrounding organs, it is remarkable that they give rise to no serious symptoms aside from the pressure they exert upon adjacent organs. Pain is not a constant symptom, and when it is present it is due more to the causes which produce the cyst than to the cyst itself. In this respect cysts of the pancreas form a counterpart to malignant disease when it affects this or neighboring organs. Emaciation is due either to coexisting affection of the gland, or to the impairment of function of important organs by pressure of the cyst. It is never so marked in these cases as in malignant disease. The supervention of fatty stools would point towards the existence of some coexisting serious lesion of the pancreas rather than towards the existence of a simple cyst of the organ. This symptom was not found present, or was overlooked, in all cases which have been operated upon. Of twenty-eight cases of stearrhœa which were compiled by Ancelet, sixteen were examined post mortem. In five of these there was occlusion of the ductus choledochus and ductus pancreaticus; in three, occlusion of the pancreatic duct alone; in one, inflammation of the pancreas and some of the adjacent organs. In the remaining cases disease of the liver and the bowels, or marasmus only, was found. In thirteen cases of pancreatic calculi collected by Johnston, in three only were fatty stools observed; in six cases, diarrhœa; in four cases, melæna; and in six cases, constipation. The presence of fat in the stools is a symptom of great importance in the recognition of pancreatic disease, but that it is not of absolute diagnostic significance is proved by the well-known fact that the same condition will follow upon the obstruction of the biliary passages and upon affections which impair the functional activity of other organs of digestion.

Obstruction of the principal duct impairs digestion more than when its distal extremity or one of the accessory ducts is involved. The actual illness of the patient is usually preceded for a variable length of time by more or less marked symptoms of gastro-intestinal derangement, accompanied in some instances by pain in the region of the pancreas.

A peculiar color of the skin, which by some is believed to be characteristic of pancreatic disease, must be mentioned, as it was observed in several cases of calculous affection and cysts of the pancreas. The appearance presented by these patients is variably described as being unhealthy, pale yellow, dirty, or earthy. The intimate relations of the cyst to the cœliac plexus will explain the cause of cœliac neuralgia which is met with in some of these cases. Atrophy of the cœliac plexus from long-continued pressure may give rise to mellituria, for the same reason that Klebs has affirmed that partial extirpation or atrophy of the cœliac plexus will cause the presence of sugar in the urine. Diverse diseases of the pancreas have also been known to produce diabetes mellitus. Cases of this kind have been reported by Cowley (1788), Bright, Elliotson, Frerichs, Fles, Hartsen, Silver, Recklinghausen, Munk, Seegen, and Friedreich. Klebs demonstrated by his experiments that complete extirpation of the pancreas or ligature of its duct invariably gave negative results, as far as diabetes was concerned, and this may account for the fact that no sugar was found in the urine of the cases reported in this paper. The cyst, when examined early, before it has attained considerable size, is always found in the region normally occupied by the pancreas. The exact location, however, is not always uniform, as it will depend upon the portion of the pancreas from which the cyst has taken its primary origin. It may be situated below the right lobe of the liver, as in Kulenkampff's case; in the epigastric region, as in Gussenbauer's case; or in the left hypochondrium, as in my case. When the tumor has attained a large size, or occupies the whole abdominal cavity, it will be difficult, and in the latter instance impossible, to determine by any known means its primary origin. In such cases it is of paramount importance to study its relations to adjacent organs. The tumor is invariably situated in the bursa omentalis, and from this point, as it increases in size, it encroaches upon the space occupied by adjacent organs. The stomach is pushed forward in all cases, and later to the right. The transverse colon is displaced downward, the spleen to the left, and the diaphragm and contents of the chest upward. The cyst being in direct contact with the diaphragm, it usually ascends and descends with the respiratory movements of the chest.

In doubtful cases it will become necessary to inflate the stomach and colon, with a view to ascertain their position relative to the cyst. If the patient is a female, and the tumor occupies the entire abdominal cavity, it will simulate cystic disease of the ovary so closely that a differential diagnosis between the two is impossible. The cases reported by Luecke, Bozeman, and Rokitansky furnish adequate proof of the correctness of this statement. The proximity of the abdominal aorta is such that the impulse of the artery is imparted to the tumor, which, however, pulsates only in one direction,—away from the artery,—a fact which will always distinguish it from an aneurism. Unless the cyst is exceedingly tense, a sense of fluctuation is always imparted by palpation. Palpation is rendered difficult on account of the deep location of the pancreas and the rigidity of the recti abdominis muscles. The normal pancreas can be felt only under certain favorable conditions. Concerning this point Sir William Jenner says, "By deeply depressing the abdominal walls about a hand's breadth below the umbilicus, and then rolling the subjacent parts under the hand (the stomach and colon must be empty), it might be possible to detect it in an individual who is thin and whose tissues are lax." In case the examination is rendered difficult on account of great rigidity of the abdominal muscles, this obstacle can be overcome by examining the patient while under the influence of an anæsthetic. An exploratory puncture with a fine and perfectly aseptic needle of a hypodermic syringe will not only add material diagnostic information by revealing the character of the cyst-contents, but will also settle the question as to the existence or absence of adhesions between the cyst-walls and the parietal peritoneum. In the differential diagnosis the following affections will come up for consideration:

1. Malignant disease of the pancreas or adjacent organs.
2. Aneurism.
3. Echinococcus of the liver, the spleen, or the peritoneum.
4. Affections of the retro-peritoneal lymphatic glands.

5. Hydro-nephrosis or pyo-nephrosis.
6. Cystic disease of the suprarenal capsule.
7. Circumscribed peritonitis, with exudation.
8. Ascites.
9. Cystic disease of the ovary.

Prognosis.—Physiologists are agreed in assigning to the pancreas a most important function in the digestion of organic food. We know that by a special ferment it assists in the transformation of starch into dextrin and sugar and in the digestion of albumen and fat. We should naturally expect that in diseases of this organ the digestion of these substances would be impaired in proportion to the amount of gland-tissue destroyed. On the other hand, we have abundant evidence to show that even total disorganization or destruction of the pancreas is not incompatible with normal digestion and perfect health. It would appear that in the absence of the pancreatic secretion other organs assume a vicarious action and digestion proceeds unimpaired. It is also important to remember that even a large cyst of the pancreas does not necessarily result in extensive destruction of the gland, and that the remaining gland-tissue continues to secrete and discharge a sufficient amount of pancreatic juice. In Bozeman's case the cyst occupied the entire abdominal cavity, and yet at the operation the greater portion of the gland was found healthy in structure. The integrity of the structure and function of the gland depends less on the pressure of the cyst than on the causes concerned in its production.

The dangers arising from the cyst itself consist in (1) its interference with the functions of other abdominal organs by pressure, and (2) rupture of the cyst and escape of its contents into adjacent hollow organs or the peritoneal cavity. Compression of the stomach and interference with its normal peristaltic action constantly occur when the cyst has developed to any considerable size. When such is the case, vomiting soon after meals takes place, as was noted in a number of cases which have been reported. When the cyst is of very large size, nearly all the abdominal organs suffer by compression, and both digestion and absorption are impaired by mechanical pressure. The diaphragm being at the same time pushed upward, the heart and lungs are displaced in the same direction, and embarrassment of circulation and respiration follows as a necessary consequence. Like any other benign abdominal tumor, the cyst proves dangerous to life by interfering mechanically with the functions of more essential and important organs.

The second source of danger is rupture of the cyst and escape of its contents into adjacent organs, an accident which may be followed by immediate death from hemorrhage, or will place the life of the patient in jeopardy by suppurative inflammation in the interior of the cyst, or by peritonitis in case the contents have escaped into the peritoneal cavity. In Pepper's case the immediate cause of death was hemorrhage consequent upon rupture of the cyst into the stomach. At the post-mortem examination a large quantity of blood was found in the stomach and intestine, which had entered through an opening about half an inch in diameter, close to the proximal termination of the ductus communis. A probe passed through this opening directly entered a cyst in the head of the pancreas. A communication with any portion of the gastro-intestinal tract would almost of necessity cause infection and suppurative inflammation in the interior of the cyst, which, under unfavorable circumstances, might lead to a fatal termination from septicæmia or extension of inflammation to adjacent organs.

The prognosis may be said to depend—

1. On the nature and cause of the obstruction.
2. On the size of the cyst.
3. On the absence or presence of complications.

Treatment.—In the treatment of a pancreatic cyst the indications are the same as in the treatment of any other kind of cyst,—viz., (1) extirpation of the cyst, (2) evacuation of the cyst-contents and obliteration of the cyst.

Extirpation was attempted in Bozeman's and Rokitansky's cases; in the former instance success was complete, in the latter the operation was not completed, and the patient died a few days afterwards, of septic peritonitis. It is proper to state that in both cases the operation was done for the removal of a supposed ovarian cyst, and that a correct diagnosis was made in the first case during the operation, after the pedicle was traced to the pancreas and the intact portions of the gland were identified; in the second case the post-mortem examination revealed the true nature and location of the cyst. The brilliant result obtained by Dr. Bozeman is well calculated to stimulate others to follow his example. Extirpation of the cyst would guard most effectually against the formation of a permanent pancreatic fistula, but, on account of the deep location of the pancreas, the shortness or absence of a pedicle, and the many obstacles thrown in the way of the operator by adjacent organs, the procedure is surrounded by innumerable difficulties, and, in the present state of our science, is of doubtful propriety. Simple evacuation of the cyst-contents by means of the aspirator presents two principal objections against its adoption in the treatment of cysts of the pancreas:

1. Escape of cyst-contents into the peritoneal cavity.
2. Reaccumulation of secretion.

Reasoning from analogy, we should naturally expect that when pancreatic juice is brought in contact with the peritoneum it would produce a destructive effect thereupon by its digestive properties, or that such contact might even be followed by diffuse peritonitis. In opposition to this assumption, it is affirmed that in experiments on the pancreas the pancreatic juice frequently escapes into the abdominal cavity from the canula introduced into the pancreatic duct, without any bad results on the animals. Concerning this point Heidenhain says, "The animals do not suffer from this circumstance, as the duct is regenerated in spite of the wounded surface being bathed in the secretion. Nevertheless, it is difficult to explain this. Why do not the wounded and suppurating tissues undergo digestion by the pancreatic juice? The efficacy of the albumen ferment is destroyed in some way, I presume, probably by being changed into zymogen, the living tissues having the same effect on the juice as Podolinski observed by treating the pancreatic juice with pulverized zinc or yeast ferment." Although small quantities of pancreatic juice may escape into the peritoneal cavity of an animal without any serious consequences, we have no evidence to show that the peritoneal cavity in man is possessed of the same immunity against such accident, and it would not be prudent to expose the patient to such risk until more light is thrown on this subject by further observation and experiment. At the same time we must not forget that pure pancreatic juice is found only in small cysts, as the contents of large cysts have undergone various transformations, and are mixed with different accidental products, which might prove an additional source of danger in producing peritonitis. In all the cysts where a pancreatic fistula was established, the artificial opening continued to discharge the secretion for a variable period of time, and in two cases the discharge had not ceased at the time the report was made, and hence reaccumulation would have been inevitable in case the fluid had been removed by aspiration. For these reasons, the treatment by aspiration should be limited to cysts of moderate size, and where adhesions have formed between the cyst and the anterior walls of the abdomen. In cases presenting these favorable conditions, aspiration deserves a trial, and may be repeated as often as required, or until symptoms arise which call for more radical measures. The needle should always be thoroughly disinfected by passing it through the flame of a spirit-lamp and by dipping it in a five-per-cent. solution of carbolic acid. The puncture is made obliquely, so as to prevent the formation of a fistulous opening. The fluid should be withdrawn slowly and the cyst emptied as completely as possible.

After the operation gentle pressure should be made over the cyst, by applying a compress and elastic bandage. The safest and at the same time the most efficient treatment consists in establishing a pancreatic fistula. The operation which accomplishes this purpose most safely and in the shortest time consists in exposing the cyst by an incision and stitching its walls to the margins of the wound. The same aseptic precautions must be observed before, during, and after the operation as in any other abdominal operation. The stomach being generally pushed forward, upward, and towards the right by the cyst, it is advisable to empty this organ completely, as a preliminary measure, by abstinence from food and by the use of the siphon irrigator. Except in my case, the incision has always been made in the linea alba. It seems to me that the incision should be made over the most prominent part of the tumor, and as nearly as possible over the seat of the obstruction. In following this rule, we select the place where we are most apt to find adhesions, at the same time that we establish the straightest and most direct route to the primary origin of the cyst. An incision through the linea alba, or parallel with the costal arch, will afford the easiest access, with a minimum risk of injury to important parts. The external incision should be at least four inches in length, while the peritoneum should be opened only to the extent of two inches, for the purpose of making an exploratory examination, the opening to be enlarged as occasion may require. If adhesions are found between the cyst and the omentum and the parietal peritoneum, the cyst is punctured with an exploring needle, and, if the diagnosis is corroborated, the operation is finished by incising and draining the cyst. If no adhesions are found between the omentum and the peritoneum, the former is incised so as to expose the cyst-wall, when either of the following plans may be pursued. The parietal peritoneum is stitched to the skin with catgut. The margins of the omental wound having been pushed back under the abdominal walls so as to expose the cyst freely, the wound is packed from the bottom with iodoform gauze, and an antiseptic dressing is applied and retained for six or eight days, or until adhesions have formed between the cyst and the margins of the wound which effectually shut off the peritoneal cavity, when the cyst is incised and drained.

Suturing of the cyst-wall to the margins of the wound as a preliminary operation should never be resorted to, as on account of the thinness of the cyst-walls there is danger of escape of fluid into the peritoneal cavity from the punctures made by the needle, an occurrence which the procedure was intended to obviate. With proper care, however, the operation can be completed at once. The cyst-wall is grasped with two many-toothed forceps, and drawn forward so as to bring it in accurate and close contact with the margins of the wound, when the fluid is removed with an aspirator or a trocar with the same care as would be employed in emptying an ovarian cyst. As the cyst becomes empty it is pulled through the wound, which obviates any further danger of escape of fluid into the peritoneal cavity. When the cyst is nearly empty it is freely incised and sutured to the peritoneal lining of the abdominal wound. The drainage-tube should be fully three-quarters of an inch in diameter, and must reach from the bottom of the cyst to the surface of the wound. After emptying the cyst completely by compression, and placing the patient on his side, a large Lister dressing is applied, for the purpose of guarding against infection and to absorb the secretions. Frequent change of dressing may be required on account of copious escape of pancreatic secretion. Past experience would dictate the advisability of protecting the skin against the digestive action of the pancreatic juice by applying freely carbolated oil. The antiseptic dressings should not be abandoned until the peritoneal cavity has become completely closed by firm adhesions and the size of the cyst has been reduced to a fistulous tract. The drainage-tube is shortened from time to time, as the depth of the fistulous opening is diminished by obliteration of the cyst from the bottom of the tract. The speedy obliteration of the cyst will depend on the continuance, abatement, or removal of the obstructing cause, or the condition of the gland-tissue distal to the seat of obstruction. If the stricture in the common duct of the pancreas is complete and of a permanent character, the obstruction will continue, and, if healthy gland-tissue remains on the distal side, the fistula will continue to discharge pancreatic juice. If the inflammation which caused the obliteration of the duct subsides and the passage again becomes permeable, the natural outlet will be again established and the artificial duct will become obliterated. If an impacted calculus has caused the retention and the fistula continues to discharge, a careful examination should be made to detect the calculus, and, if found, an effort should be made to remove it through the fistulous opening. If the obstruction has become permanent and the gland-tissue on the distal side has become destroyed either by the cause or causes which produced the obstruction or by the intra-cystic pressure, that portion of the organ has been deprived of its functional capacity, and, as no pancreatic juice is secreted, definitive obliteration of the cyst and permanent closure of the fistulous tract will take place in a comparatively short time.

CARCINOMA.

It is asserted by some pathologists that primary cancer of the pancreas does not occur, and that in cases where this organ is the seat of the lesion it occurs as a secondary affection, having reached it by extension from an adjacent organ, especially from the pyloric extremity of the stomach. While this may be true in many cases, a considerable number of specimens have been examined where the disease occurred here as a primary affection. Suche appears to have examined a specimen which affords a good illustration of primary cancer of the body of the pancreas. The middle of the gland was converted into a hard, irregular, nodulated mass, the size of a fist, resting directly upon the aorta, which imparted to it pulsation during life. When cut into, the tumor grated under the knife, and the cut surfaces presented a laminated appearance. The substance of the tumor was traversed by numerous large veins; both extremities of the pancreas were healthy, and no secondary nodules could be found in any portion of the body. A primary cancer of the pancreas is also described by Schupmann, where the tumor had formed adhesions with the spleen, while the liver contained a number of metastatic deposits. The terminal extremity of the pancreatic duct contained a cylindrical calculus with a number of arborescent projections, which corresponded to the contributory ducts. In another case, reported by Récamier, the cancerous tumor, which involved the tail of the pancreas, was connected with the left kidney and compressed the ureter. The right half of the pancreas was healthy, the diseased portion gray, hard, and lardaceous. The pelvis of the left kidney, in consequence of the compression of the ureter, was hydronephrotic. The remaining organs were healthy.

Bright, in 1832, reported a number of cases of primary carcinoma of the pancreas, with a special view of illustrating the effect which disease of this organ has upon the digestion of fat. In three out of eight cases he noticed fatty diarrhœa, and he was inclined to the belief that this symptom, when present, is almost pathognomonic of the existence of disease of the pancreas. In all cases the fatty diarrhœa was associated with jaundice. According to Da Costa, cancer of the pancreas is more frequent in the male than in the female, and preferably attacks people over forty years of age. That even young children are not exempt from cancer of this organ is well shown by a case recently reported by Kühn.

The patient was a child only two years of age. The most prominent symptoms were progressive anæmia and obstinate diarrhœa. Syphilis could be excluded. Towards the last there was general anasarca and the liver was enlarged, but the spleen and the lymphatic glands appeared normal. Careful auscultation and percussion revealed nothing abnormal in the organs of the chest; the urine was normal, except that it contained a trace of albumen. At the post-mortem a slight serous effusion was found in the left pleural cavity. The lower lobe of the left lung was consolidated and brownish red in color. In the solid portion of the lung a white, firm nodule about the size of a hazel-nut was found. The upper lobe of the right lung contained an infarct nearly the size of the nodule in the left. The abdominal cavity contained some serum. Kidneys normal in size, capsule non-adherent, parenchyma granular, light-red color, pyramids more dark. Pancreas hardly of normal size, contained a firm tumor, the surfaces of a cross-section presenting a grayish-white appearance. Under the microscope this tumor showed the characteristic structure of a cylindrical-celled carcinoma. The tumor had evidently started from an embryonal matrix of epithelial cells in some portion of the pancreatic duct and had given rise to embolic dissemination in the terminal branches of the pulmonary artery.

Another case of rapidly-growing primary carcinoma of the pancreas in a child only six months old has been reported by Bohn.

Carcinoma of the pancreas usually appears as a firm tumor or scirrhus, with a well-developed connective-tissue reticulum. Other varieties of carcinoma have been described. Thus, Wagner observed a cylindroma, and Lücke and Klebs have each met with the colloid variety. The primary starting-point is usually in the head of the organ, whence it extends in all directions. By extension within, it successively invades the body and tail of the organ, until the whole gland is involved, when it forms a nodulated spherical tumor. The extension of the growth in an opposite direction soon reaches the duodenum, where it produces a narrowing or complete stenosis of that portion of the intestinal canal. A case of this kind is related by Hoelscher, where the duodenum was constricted to such an extent that it was entirely impermeable, and the patient suffered for several days from symptoms of intestinal obstruction. While cancer of the stomach is liable to extend to the pancreas, the converse is not frequently observed. When the carcinoma develops primarily in the pancreatic ducts, it belongs to the variety called cylindroma. The lymphatic glands in the vicinity of the pancreas are invariably affected during the later stages of the disease.

Symptoms and Diagnosis.—Stearrhœa is an important but not an infallible symptom of cancer of the pancreas. It is attributed to an absence of the pancreatic juice in the intestinal canal, caused either by obstruction in the duct or by suspension of the physiological function of the organ by the neoplastic infiltration. Epigastric pain is an early and important symptom, and is the result of compression of the cœliac plexus by the tumor. The pain often assumes a neuralgic character, and is usually not aggravated after taking food. Vomiting is a frequent symptom, and the matter ejected is generally a watery fluid, sometimes stained with bile. Constipation is an almost constant symptom. Progressive emaciation and anæmia attend malignant disease in any locality, but are unusually well marked in cancer of the pancreas. When the disease extends towards the duodenum, jaundice occurs from stenosis of the bile-ducts by compression or direct invasion by the neoplasm. Bruen has called attention to some forty cases of jaundice due to primary carcinoma of the head of the pancreas, lately reported by another observer, from which it is demonstrated that jaundice is an invariable symptom of primary scirrhus of the head of the pancreas, while it is uncommon when the disease is secondary or affects the body or the tail of the organ.

The most reliable evidence is the appearance of a tumor in the epigastrium behind the stomach. The difficulty of examining the pancreas during health by palpation is appreciated when a physical examination is to be relied upon in locating tumors in this locality. The normal pancreas can be felt only under the most favorable conditions through a thin and relaxed abdominal wall, but in determining its relative size this method of examination affords little reliable information. A cancer of the pancreas, where it can be felt by palpation, appears in the epigastrium as a hard, immovable or only slightly movable tumor, which is evidently deeply seated in the abdominal cavity. Under favorable conditions the connections of such a tumor with the pancreas can sometimes be demonstrated during life, but a positive diagnosis becomes impossible when, as in most of the cases hitherto recorded, it constitutes merely a part of a general tumefaction of the abdomen. As the tumor is in such close proximity to the abdominal aorta, the pulsations of this vessel are imparted to the tumor, and a bruit may even be heard over the compressed vessel; but, in contradistinction to aneurism, the pulsation is felt in only one direction, and the bruit disappears when the patient is placed in the knee-elbow position, as the tumor is lifted from the vessel by the force of gravitation.

That the tumor cannot always be felt is evident from the statement made by Da Costa that he recognized it in only thirteen out of the one hundred and thirty-seven cases he reported; and Bigsby, in an analysis of fifteen cases, alludes to its being recognized in only four.

From what has been said, it will be seen how uncertain the symptoms are in the diagnosis of cancer of the pancreas. A satisfactory conclusion can be reached only after a careful consideration of the history of the case combined with a systematic elucidation of all the symptoms presented, and more particularly by resorting to the advantages to be derived from a systematic and careful study by exclusion.

Treatment.—A positive diagnosis of malignant disease of the pancreas is possible only after the tumor has attained sufficient size to be recognizable by palpation, consequently too late for a radical extirpation. When the disease has advanced to this stage it has already involved the greater portion of the gland, and, as a rule, has invaded important adjacent organs. Another important element in the surgical treatment of cancer of the pancreas consists in the fact that the disease, as a rule, develops primarily in the head of the organ, a location which in itself precludes the propriety of an operation. The most favorable conditions for extirpation are presented if the disease is primarily located in the tail of the pancreas and has not passed beyond the limits of the capsule of the gland. In such a case excision of the splenic extremity of the pancreas would offer a fair prospect for a permanent result without endangering, as a remote consequence, the process of digestion, as a sufficient amount of secreting structure would remain in connection with the intestine to maintain pancreatic digestion.

Billroth in two instances made a partial resection of the pancreas in removing carcinomatous tumors of adjacent organs. In one case he removed a portion of the head of the pancreas with a cancer of the pylorus, and in another case he removed the tail of the pancreas with a sarcomatous spleen. Both patients recovered from the immediate effects of the operation. In the case of partial excision of the head of the pancreas it is to be assumed that the duct was not injured, that the organ continued to secrete, and that the pancreatic juice was discharged into the duodenum through the uninjured duct. In operating upon the head of the pancreas for malignant disease which has extended to it from an adjacent organ, it is essential to preserve the continuity of the duct, so as to prevent physiological derangement of the remaining portion of the gland, an accident which would be followed by degeneration and complete atrophy, and consequently by suspension of pancreatic digestion. If an operation is performed for cancer of an adjacent organ, and the disease has extended to the splenic extremity of the gland, the operation should not be completed without removing a sufficient portion of the pancreas to guard against a local recurrence of the disease in this organ. As in cases of partial excision of the pancreas for other lesions, the pancreas should be ligated before it is divided, so as to prevent troublesome hemorrhage and at the same time guard against extravasation of pancreatic juice into the peritoneal cavity.

TUBERCULOSIS OF THE PANCREAS.

Primary tuberculosis of the pancreas is an exceedingly rare affection; indeed, some pathologists, among them Louis and Lebert, doubt its primary origin in this organ. Cruveilhier only mentions tubercular degeneration of the lymphatic glands upon the surface of the pancreas. In diffuse miliary tuberculosis of the abdominal organs Klebs could find no nodules in the substance of the pancreas on microscopical examination. But in such a condition the gland is often found in a state of parenchymatous degeneration, which has been incorrectly interpreted as the first stage of tuberculosis by Ancelet.

When the lymphatic glands around the pancreas have undergone cheesy degeneration, we sometimes find similar deposits in the pancreas, which, however, may be cheesy lymphatic glands in the substance of the pancreas itself. Hartmann mentions a case where the pancreas had disappeared completely and its place was occupied by a cheesy mass.

Bamberger found a large abscess of the pancreas in a tubercular patient in whom during life no symptoms, either objective or subjective, pointed to the pancreas as the seat of suppuration. Although the pancreas is not disposed to tuberculosis, we have reliable information that in a number of cases this gland was the primary seat of the process.

While in most of the reported cases of primary tuberculosis of the pancreas the symptoms during life pointed to disease of this organ, a sufficiently positive diagnosis to warrant a laparotomy could have been made only after a palpable tumor appeared, and by that time the disease would have passed beyond the reach of successful surgical treatment through the appearance of the miliary deposits in other organs, an occurrence which would render any operative interference unjustifiable. Should abdominal section be performed in a case of tubercular peritonitis, and should such a condition in the pancreas be found as in a case described by Aran, it would be proper to extirpate the terminal end of the pancreas exclusive of the tubercular abscess.

In a case reported by Wilson, the tubercular deposit in the pancreas gave rise to a large abdominal tumor due partly to the distended gall-bladder; and, as such a condition might present itself to the surgeon in these days of diagnostic laparotomy, it might be advisable, and to the advantage of the patient, to establish an external pancreatic fistula instead of closing the wound. Such a course would enable the surgeon to remove the cheesy material, and to disinfect the abscess-cavity and to treat its interior with iodoform, all of which, done under antiseptic precautions, would tend to modify favorably the local process.

The removal of compression of the bile-duct by the same procedure would also tend to re-establish the interrupted communication between the bile-ducts and the duodenum by removing the cause of the stenosis.

SYPHILIS.

Syphilitic lesions of the pancreas have been found, both as a tertiary manifestation of syphilis and as a congenital affection. Sometimes the entire gland, sometimes only portions of it, may be the seat of the disease: in these latter cases a circumscribed sclerosis, either with or without gummata, may be found. Lancereaux believes that many cases of sclerosis of this organ result from syphilis. In newly-born children and in the fœtus unmistakable evidence of degeneration of the pancreas in connection with hereditary syphilis has been frequently demonstrated. In such a case

Cruveilhier found the pancreas transformed into an amyloid swelling. Oedmansson found alterations in the pancreas in children suffering from congenital syphilis, consisting of extensive fatty degeneration of the parenchyma-cells and advanced interstitial sclerosis. Klebs described several gummata in the pancreas along with syphilitic changes in other internal organs of a six months' fœtus.

Birch-Hirschfeld found thirteen times in twenty-five cases interstitial connective-tissue hyperplasia in the pancreas in the hereditary syphilis of newly-born children.

Demme reports the following interesting case. At the time of birth the child weighed two thousand eight hundred and forty grammes, and exhibited a well-marked papular syphilitic eruption over the lower extremities. For ten days the child was immersed daily for a short time in warm water in which one and a half grammes of corrosive sublimate had been dissolved, with the result of improving the skin-affection. The child suffered constantly from diarrhœa, and the stools contained undigested fat. The urine contained a trace of albumen; otherwise it was normal. After the suspension of the baths inunctions of mercurial ointment in daily doses of a quarter of a gramme were used for ten days, and were followed by marked improvement. Abdominal distention and tenderness as well as the icterus which had existed were greatly diminished, and the weight of the child increased considerably. Diarrhœa less, but character of stools unchanged. After this apparent improvement the symptoms again became more aggravated, and, from the effects of an exhaustive diarrhœa and progressive marasmus, the child died thirty days after its birth. On post-mortem the lungs presented a collapsed appearance and the heart-muscle was of a grayish-brown color. In the walls of the left ventricle near the apex several gummata were found. Slight ascites; liver normal in size and structure, with the exception of a few gummata in the lobus Spigelii. Pancreas firm, small, and grating under the knife. Serous coat of duodenum hyperæmic, with isolated spots of ecchymosis; spleen and kidneys normal. In this case the syphilitic lesion in the pancreas had advanced to the stage of sclerosis.

Demme's treatment, as described above, should be imitated in all cases of congenital syphilis of the pancreas.

FUNCTIONAL DISORDERS OF THE LIVER, JAUNDICE, AND DISEASES OF THE DUCTS AND OF THE PORTAL VEIN.

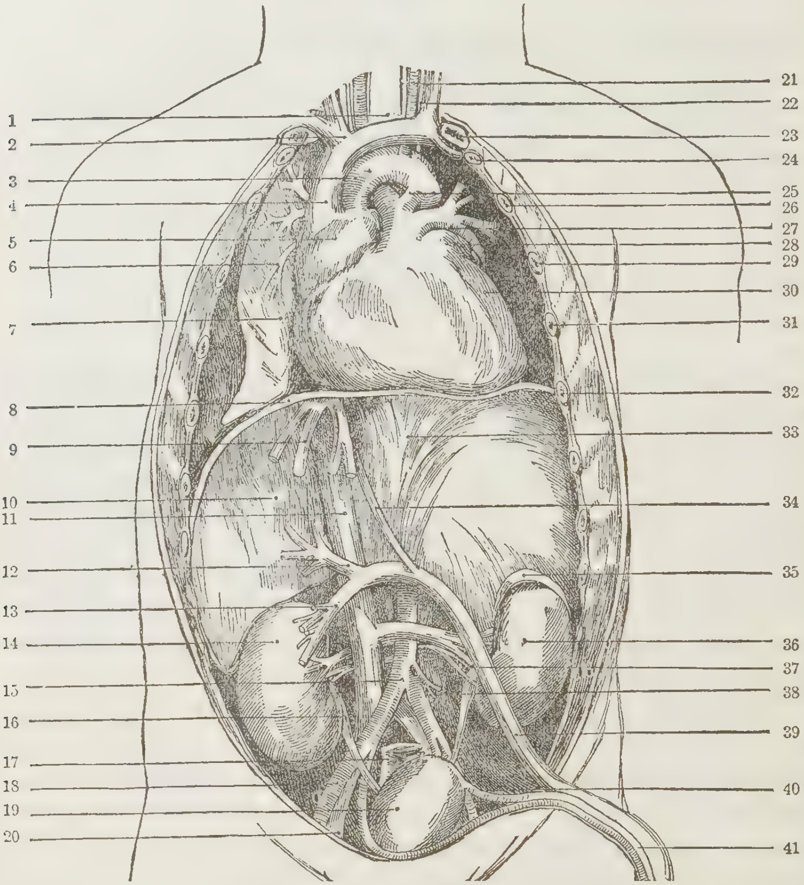
By HENRY DWIGHT CHAPIN, M.D.

In considering the subject of affections of the liver, the first things to attract attention are the relatively large size and the apparent functional importance of this organ in early life. For a correct understanding of these facts we must go back and consider some of the phenomena of fœtal life. The liver is then a very important factor in the circulatory system, while the lungs are largely inactive. It is somewhat surprising to learn that in the mature fœtus the liver holds a quarter or more of the entire volume of blood, and that it is greater in size than both lungs. A brief review of some peculiarities of the fœtal circulation will help to a further understanding of this subject. (Fig. 1.)

The passage of arterial blood from the placenta to the fœtus takes place through the umbilical vein in the umbilical cord. At the umbilicus the umbilical vein enters the abdomen of the fœtus and reaches the under surface of the liver after passing along the free margin of the suspensory ligament. Several branches are given to the left lobe as well as to the lobus quadratus and lobulus Spigelii. The umbilical vein divides into two branches at the transverse fissure. The larger branch, after being joined by the portal vein, enters the right lobe. The smaller branch forms the ductus venosus, which joins the left hepatic vein as it enters the inferior vena cava. The blood which leaves the placenta for the nutrition of the fœtus through the medium of the umbilical vein reaches the inferior vena cava in three different ways. The great bulk of it circulates through the liver with the portal venous blood and passes into the vena cava through the hepatic veins. A part enters the liver directly by branches of the umbilical vein, and, after circulating through this organ, reaches the vena cava also by means of the hepatic veins. Finally, a small quantity passes directly through the ductus venosus and by its junction with the left hepatic vein enters the vena cava.

As the lungs of the fœtus are solid and almost impervious, the placenta of the mother performs the double function of a respiratory and of a nutritive organ. After the venous blood is received from the fœtus it must be returned reoxygenated, and nearly the whole of this purified stream is

Fig. 1.



The Fœtal Circulation, showing the Relative Position of the Organs, drawn by Dr. McClellan from dissections and preparations in his cabinet.—1, the trachea, with the carotid arteries on either side; 2, the right innominate vein, overlying the innominate artery; 3, the arch of the aorta; 4, the superior vena cava; 5, the right auricle; 6. the right pulmonary vessels passing into the unexpanded lung; 7, the right lung packed in the back of the thorax; 8, the diaphragm; 9, hepatic veins; 10, the right lobe of the liver, dissected to show branches of portal and hepatic veins; 11, inferior vena cava; 12, right branch of portal vein; 13, portal vein coming from the intestines, which are removed; 14, right kidney; 15, bifurcation of aorta into the two common iliac arteries; 16, right ureter; 17, rectum tied; 18, right external iliac artery and vein; 19, bladder; 20, right hypogastric artery; 21, left recurrent laryngeal nerve; 22, left pneumogastric nerve; 23, left clavicle; 24, first rib; 25, ductus arteriosus; 26, second rib; 27, left pulmonary vessels; 28, left auricle; 29. third rib; 30. left ventricle; 31, fourth rib; 32, fifth rib; 33, crura of diaphragm; 34, ductus venosus (the left lobe of the liver, stomach, pancreas, and spleen are removed); 35, left supra-renal capsule; 36, left kidney; 37, left renal vessels; 38, inferior mesenteric artery; 39, umbilical vein; 40, left hypogastric artery; 41, umbilical cord.

carried to the liver by the umbilical vein and circulates through this organ before reaching the vena cava and the general circulation.

The large size and the importance of the liver in fœtal life are thus understood by considering it a sort of intermediary organ between the placenta and the general circulation, as far as the reoxygenated blood is concerned.

At birth the communication between the placenta and the liver and portal vein, by means of the umbilical vein, is severed by cutting the cord. The lungs at once inflate and assume the respiratory function. The umbilical vein begins to shrink, and becomes completely obliterated between the second and fifth days after birth. It finally becomes the fibrous cord known as the round ligament of the liver. The ductus venosus also usually becomes completely obliterated a few days after birth.

Although the liver has now lost its preponderating importance in the economy, it still remains relatively larger and heavier than in later life. The diminution of the organ is due to its altered blood-supply, and is especially marked in the left lobe. The loss of weight that begins at birth continues, so that there is a direct ratio from infancy to old age in this relative diminution. At birth the liver-weight is in proportion to the whole body as 1 to 28; in infancy, 1 to 20; at puberty, 1 to 30; in adult life, 1 to 35; in middle life, 1 to 40; in old age, 1 to 45. The following is taken from a table of Frerichs in reference to the relative and absolute weight and size of the liver under normal conditions at different ages.[1]

AGE.	WEIGHT		RELATIVE WEIGHT OF LIVER TO THAT OF BODY.	DIMENSIONS OF LIVER.				
				Length.		Breadth.		Thickness (greatest).
	OF BODY.	OF LIVER.		Right Lobe.	Left Lobe.	Right Lobe.	Left Lobe.

Upon ligation of the umbilical cord and ending of the placental circulation there follow great changes not only in the infant's circulation but also in the blood itself. These changes appear to be at first of a degenerative nature, and follow a more perfect oxygenation of the blood. Immediately after birth the red corpuscles number six or seven millions per cubic centimetre, while by the fourth or fifth day the number has dropped to four or five millions. According to the observations of Hofmeier,[2] the size of the red corpuscles at birth is very variable, and the white corpuscles are often in greater proportion than in adults' blood. Various ring-like forms have been seen in the blood of new-born infants, which are supposed to be the skeletons of red corpuscles after the coloring-matter has disappeared.

---

[1] A Clinical Treatise on Diseases of the Liver, 1879.

[2] Zeitschr. f. Gynaek. u. Geburtsheilk., xiii. 12.

Hæmoglobin is thus transferred from the stroma of the corpuscle to the plasma. As a result of the destruction of red and white corpuscles, there will be a relatively large quantity of fibrin-ferment in the blood in conjunction with the hæmoglobinæmia. In healthy infants the liver will convert the liberated hæmoglobin into biliary coloring-matter in a few days, which will be partially liberated by the fæcal discharges and urine. Silbermann[1] sums up the condition of the blood as follows:

1. The blood of the newly-born contains corpuscles which vary greatly in size, and also the so-called "shadows."
2. It is richer in fibrin-ferment than is the blood of adults.
3. These peculiarities are due to the liberation of hæmoglobin and its transfer to the plasma.
4. The richness in fibrin-ferment of the blood of the newly-born predisposes them to disease.
5. All disease-processes in the newly-born which involve great destruction of the albumen of the circulation are especially dangerous to life.

It is strange that morbid conditions referable to the liver should not be more frequent in early life, and particularly during the first few days of life, when we consider the profound changes in its circulation following the obliteration of the umbilical vein and ductus venosus, together with the degenerative changes in the blood going on at the same time.

ICTERUS.

Synonymes.—Jaundice; French, Ictère; German, Gelbsucht.

The word icterus seems to have been derived from two sources. Some refer its original derivation to an animal, the weasel, having yellow eyes. Others consider the term to be derived from the bird called icterus that was supposed to die upon being viewed by a jaundiced patient, the latter immediately recovering. Jaundice comes from the French word "jaune," meaning yellow, and signifies a yellowish coloring of the skin. The German term "gelbsucht" is not now much used, being superseded by icterus.

There are many grades of icterus, due to several causes and appearing at different periods of life.

ICTERUS EMBRYONUM.

The earliest occurrence of icterus is where the fœtus of a jaundiced woman is found to have this affection. Frerichs considers that the woman must be jaundiced for several weeks before the fœtus can be likewise affected, since in cases where the mother was jaundiced from five to fourteen days before delivery the fœtus was free from the disease. Icterus embryonum is an exceedingly rare affection, very few cases being reported in the literature of the subject. In some instances the jaundiced infants have been born before term, and in others born dead at full term. Legg[1] quotes two cases from Wrisberg in which autopsies had been made and a dissection showed the gall-ducts to be plugged with mucus. The prognosis is not always fatal, as occasionally recovery has taken place.

---

[1] Jahrb. für Kinderheilkunde, xxvi. 2.

ICTERUS NEONATORUM.

New-born babies so frequently become jaundiced that this especial liability deserves a separate name and different consideration from the same affection occurring in older children. Many different theories have been advanced to explain the etiology and frequency of icterus at this period of life. All the cases may be divided into two general classes,—the mild and the grave or malignant. The former class will be first considered.

Mild Icterus Neonatorum.—Two divergent theories have been advanced to account for the milder grade of icterus neonatorum. The first considers the jaundice to be purely of hæmatic origin. The excessive amount of hæmoglobin which is present in the blood at this early period is decomposed under the influence of some fermentative agent, and an elimination of this coloring-matter produces the jaundice. The second theory regards the jaundice as hepatic. Bile is first formed in the liver and then carried into the circulation, the reabsorption being due either to congestion of the blood-vessels or to œdema of the hepatic tissue. It seems highly probable that both these theories may be true in different instances, and doubtless many cases of icterus neonatorum are to be satisfactorily explained only by taking into consideration a morbid condition of both the blood and the liver, thus combining the hæmatic and hepatic theories.

The experiments of Stern are interesting in this connection. He succeeded in removing the liver from pigeons and producing hæmoglobinæmia, but failed in inducing icterus. From these experiments the presence of the liver would seem to be necessary to produce the jaundice, in addition to a large amount of coloring-matter circulating in the blood. It is generally considered that the coloring-matter of the bile is a derivative from the coloring-matter of the blood, but the transformation takes place by means of the liver. In vigorous, healthy infants the liver will change the liberated hæmoglobin into biliary coloring-matter in a few days, and this will be eliminated by the excreta. If the infant is feeble or diseased this transformation and elimination will not so readily take place, and jaundice will be one of the results. The transference of bile into the blood may be favored by an anatomical peculiarity at birth. Thus, the theory of Quincke explains certain cases of icterus on the ground that the ductus venosus may remain open for some time after birth, thereby allowing a part of the portal blood containing bile to pass directly into the general circulation. Ashby reports a case in which an autopsy showed the ductus venosus to be widely open in a jaundiced infant who died on the eleventh day. He believes that this duct is liable to remain open longer in feeble and immature infants than in more vigorous ones. Jaundice is certainly much more likely to develop in the former than in the latter class of infants. The resorption theory of Frerichs considers that the pressure in the portal capillaries is greatly lessened upon the cutting off of the placental circulation. Following this decreased tension, the bile-capillaries will be subjected to an increased tension, which will be aggravated by the secretion of bile taking place at birth. An effusion of bile will then ensue, with absorption into the lymphatics or veins of the liver, and the bile will thus reach the blood in large quantities. Silbermann,[1] who has given this subject a good deal of thought and investigation, reaches the following conclusions:

---

[1] Bile, Jaundice, and Bilious Diseases, 1880.

1. Icterus neonatorum is icterus of resorption, and, therefore, hæmatogenous in character.

2. The biliary engorgement is seated in the biliary capillaries and interlobular bile-ducts, which are compressed by the dilated branches of the portal vein and the capillary blood-vessels of the liver.

3. This engorgement of the vessels is effected by a change in the circulation of the liver, occurring soon after birth, which is one of the indications of a change in the blood-plasma.

4. This change, which is induced by the destruction of many blood-corpuscles soon after birth, consists in a kind of blood-fermentation.

5. The more feeble the infant the more intense will be the icterus, for in such a child the destruction of corpuscles and the consequent blood-changes will be much more decided than in a vigorous child.

6. As a consequence of the destruction of so many red corpuscles, there is abundant material for the formation of biliary coloring-matter, and, under the influence of the fermentation-process alluded to, this coloring-matter accumulates for a long time and in considerable quantity in the hepatic vessels.

D'Espine and Picot[2] sum up their consideration of the pathology of benign icterus by stating that in all cases the ordinary icterus of the newly-born, without our being able to affirm that it may be always due to the same cause, presents clinically the same characteristics as the icterus due to an active or passive hepatic congestion.

Symptoms.—The intense congestion of the skin observed during the first few hours or days of life often produces a yellowish coloration that cannot be considered a jaundice, since it is not dependent upon the secretion of bile. It is of the same nature as the discoloration of the skin following an ordinary cutaneous bruise. The yellow tint is at first seen only on deep pressure, but as the erythema fades the yellowness increases. The conjunctivæ are not colored, and the urine appears normal. This yellowness is usually first noticed on the second day, and may continue a few days or a week.

---

[1] Arch. f. Kinderheilk., Bd. viii. H. 6.

[2] Maladies de l'Enfance, 1884.

The term "true icterus" can be applied only to those cases in which the yellow discoloration of the skin is caused by a staining by the bile-pigments. This more often occurs in cases of prolonged or difficult labor, in infants born asphyxiated or before term, and in generally feeble infants. It is very frequently seen in foundling asylums. Kehrer observed jaundice in four hundred and seventy-four out of six hundred and ninety newly-born infants at Vienna. Not infrequently, however, icterus neonatorum will occur under the best hygienic conditions. It may appear as early as a few hours after birth, but usually is not well marked until the second or third day. The early invasion of this trouble is shown by the statistics of Kehrer, who found that out of four hundred and seventy-four jaundiced infants five and three-tenths per cent. were affected on the first day, sixty-two and nine-tenths per cent. on the second, and twenty-four and one-tenth per cent. on the third, while a few began from the fourth to the seventh day. In very mild cases the yellowness may appear only on the face, chest, and back, the conjunctivæ being only faintly tinted and the urine and fæces normal in appearance. If the case be more marked, the urine may be high-colored enough to stain the linen, and the yellowness may extend to the arms and abdomen. Some infants present a yellowish discoloration of the whole body, with typical clay-colored stools. In most cases the jaundice has disappeared by the eighth or tenth day. It may, however, persist for several weeks. In rare cases, after having much diminished, it reappears with renewed intensity. No matter how well marked or extensive this form of jaundice may be, it appears to cause very little constitutional inconvenience. The liver may be slightly enlarged, and occasionally there are symptoms of intestinal catarrh.

Hoffmeier has shown that the loss of weight during the first few days is much more considerable in icteric than in non-icteric infants, and that the increase in weight is slower. The general health is unaffected after the disappearance of the benign form of icterus neonatorum. In the rare cases in which death has occurred during the existence of the icterus, it has been from some other cause.

GRAVE ICTERUS NEONATORUM.—The grave form of icterus neonatorum is, fortunately, very rare, and may be produced by several different conditions. Defects in the bile-ducts will first be considered, as among the commonest causes. In some cases all the large bile-ducts have been absent; in others the ductus communis choledochus has been narrowed, obliterated, or entirely absent. Sometimes a fibrous cord has been found in place of the gall-duct. The cystic duct has been absent and the gall-bladder in a rudimentary condition. Accompanying an obliteration of the gall-ducts, a condition of cirrhosis is usually found in the liver, which will be more or less marked according to the length of time that the infant survives. The liver is generally found enlarged.

As an example of defective duct, Dr. Oxley[1] reports a case of congenital atresia of the duodenal opening of the common bile-duct, producing a large abdominal tumor. A female infant five weeks old was brought to the Infirmary in a jaundiced and emaciated condition. There was a round, globular, tense swelling of the abdomen, dull on percussion over the right side and part of the left, except the left lumbar region, where it was resonant. A canula was inserted into the upper line of the right lumbar region, and thirty-six ounces of bile flowed away in about twenty minutes. In three days the swelling had reappeared, although not so large, and sixteen ounces of bile were withdrawn. The urine was bile-stained, and the motions were like white curds. The infant died in a few days, and an autopsy showed a globular tumor, about the size of a cocoa-nut, below the free margin of the liver. The duodenum coursed over its surface and was closely adherent to it. Both the cystic and the hepatic duct were patent and opened into the tumor. The gall-bladder was of normal size, but contained no bile, and no opening into the intestine could be found. On examining the duodenum, the papilla indicating the usual orifice of the common bile-duct was seen, but it was quite impervious.

Dr. Danforth has reported a case in which the ductus communis choledochus was entirely absent, although the cystic and hepatic ducts presented a normal appearance. The child died in profound coma seventy-two hours after birth. The discoloration of the skin was of a bronzed character. Two cases are reported by Dr. A. D. Campbell in which there was deficiency of the cystic and hepatic ducts. Dr. John B. White gives the history of a jaundiced infant dying on the twelfth day. The autopsy showed an enlarged liver, with hepatic ducts presenting no abnormal appearance, but an evident constriction of the cystic duct, while the common duct was impervious throughout its length. In place of this duct there existed a fibrous cord-like band extending to the duodenum.

Dr. White[2] has collected reports of eighteen cases in which fatal jaundice was produced by some malformation or deficiency of the bile-ducts. Dr. Henry Ashby[3] reports a case of fatal jaundice in an infant of six weeks. On dissecting out the vessels in the transverse fissure, the gall-bladder was found to be undersized, with a small cystic duct which entered the common duct and passed on, being of very diminutive size, but pervious, to the duodenum. No hepatic duct could be found, the biliary duct apparently ending in the fibrous tissue present in the fissure.

An arrest or failure of proper development of the gall-ducts may occur several times in the same family. The common duct is originally a solid structure, being formed from a protrusion of the intestinal mucous membrane growing into the blastemic mass of the liver.[4] Any factor that may interfere with the normal and complete evolution of this structure will cause fatal infantile icterus. It has been suggested that maternal impressions may at times have an influence in producing such a condition. In these cases of atresia of the bile-ducts the liver is usually in a state of incipient cirrhosis. Dr. Legg has called attention to the fact that cirrhosis of the liver will follow a ligature of the ducts in animals. Jaundice that is due to obstruction or obliteration of the biliary passages may appear a few hours after birth and soon acquire a marked intensity. It often, however, does not appear for one or two weeks after birth, and at its inception presents a light yellow tint that soon becomes darker. In cases of obliteration of the cystic duct alone the jaundice may not appear until much later, possibly not until several months after birth. The yellowish discoloration of the skin may vary from day to day, at times being much more intense than at others. The conjunctivæ are yellow. The fæcal discharges lose color and have an offensive odor, while the urine stains the diaper a yellow or greenish brown. Both the liver and the spleen are usually enlarged, which partially accounts for the increase in size of the abdomen. Such enlargement is increased by the flatulent distention of the bowel produced by decomposition of food. There is marked wasting of the infant, although nourishment may be taken in large quantities. Umbilical hemorrhage is a grave and not infrequent symptom in this form of jaundice. The bleeding is not sudden and profuse, but begins as an oozing shortly after the sloughing of the navel-string. It is apt to commence at night. Death is always hastened by this accident, as exhaustion from loss of blood is added to that induced by indigestion and malassimilation. There may also be a sort of general purpura, bleeding taking place from the nose, mouth, or stomach. It has been suggested that the umbilical hemorrhage is due to the portal congestion that is secondary to cirrhosis. Since the circulation of the liver is much obstructed, the blood passes to the ductus venosus from the left portal vein and thus reaches the umbilicus. The vessels are here not strongly enough closed to resist this pressure, and hence bleeding results. Children may live for several months with impervious or defective bile-ducts, although death usually takes place earlier, from lack of nutrition. Where umbilical hemorrhage supervenes, however, a fatal ending is not long to be averted. Death may take place in a few hours, or, at most, in a few days.

[3] Archives of Pediatrics, September, 1884.

[4] Glaister, London Lancet, vol. i., 1879.

Another grave form of icterus in the newly-born is seen in connection with septic poisoning that is generally accompanied by umbilical phlebitis. The umbilicus is a very vulnerable spot for the entrance of septic poisons shortly after birth. Upon ligation of the cord, the blood that remains in the umbilical veins forms small thrombi, that should gradually harden and in time become calcified, forming a fibrous cord in the same manner as in the ductus arteriosus and ductus venosus. In these latter structures the formation of thrombi is never accompanied by grave consequences, since their internal situation prevents the access of irritating agents. Infected air or pus, however, can readily enter the umbilical vein from the umbilicus, and thus start up umbilical phlebitis and general septicæmia. There is a constant alteration after birth in the blood-pressure in the umbilical vein, due to the action of the heart and lungs, by which a sort of flux and reflux is produced. This suction-action favors an infection of the system when the contents of this vein become septic. This grave accident is liable to occur when the mother is in a septic condition. The poison may be introduced by bacteria, which are probably the same agents that produce puerperal fever. In these cases of sepsis there is a puriform or yellow softening of the thrombi that fill up the umbilical vein. This softened matter consists of pus-corpuscles and finely granular matter containing micrococci. This sets up an inflammation not only in the vessel itself, but also in the surrounding tissues. Infective emboli may be carried to various parts of the body. As the micrococci enter the umbilical vein from the umbilical fossa, owing to the perviousness of this vessel, the structures near at hand, especially the liver, bear the first brunt of the septic inflammation. The latter organ is usually found much diseased or degenerated.

Dr. J. L. Smith[1] reports a case in which an infant who was born healthy began to be feverish on the fifth day, which was followed by a series of abscesses indicating septic infection. The cord separated at the usual time, and the umbilicus appeared healthy. When the child was two months old, a prominence appeared half an inch above the umbilicus, which was punctured in a week, when bile instead of pus escaped. The opening closed soon afterwards, and subsequently a discharge of bile occurred from the umbilicus, which continued until death, at the age of eight months. At the autopsy a probe was passed from the umbilicus into and along the umbilical vein. The umbilicus seemed normal, except a small cicatrix at its right. The umbilical vein was dilated to about twice its normal size, its walls were infiltrated and thickened, and it contained yellow, thickened bile. One of the branches of the vein traced into the liver opened into an abscess about the size of a walnut, and contained thick pus, and through this abscess a communication had been established between the umbilical vein and the bile-ducts. The gall-bladder and the hepatic and cystic ducts contained bile and appeared normal; and the liver, except for the abscess, presented a normal appearance. The abscess was in the right lobe, near its posterior border, and extended to the superior surface of the liver. The umbilical vein contained bile, with perhaps some bile-stained pus, but no blood. In these cases there may be inflammation of the umbilical artery as well as of the umbilical vein.

This septic form of jaundice comes on shortly after birth, usually within a few days, and is soon well marked. It is presumably due to pressure on the bile-ducts by swelling of the connective tissue around the branches of the portal vein in the liver. This form of jaundice is clinically distinguished from other varieties by the constant elevation of temperature and by other symptoms of general septic infection. If the infant lives long enough, objective signs of peritonitis will probably develop, and sometimes of empyema or even of meningitis. In all cases evidences of severe illness and prostration are present. Cutaneous, mucous, or visceral hemorrhages may supervene at any time. The abdomen is generally swollen and tender, and dirty-looking pus may be seen oozing from the navel: slight pressure around the umbilicus will often cause the appearance of this pus if it is not otherwise apparent. The fæcal discharges may be of a natural appearance, but the urine is usually very highly colored. The infant refuses nourishment, and may be troubled with vomiting of a greenish matter. Severe nervous symptoms, such as convulsions or coma, are apt to supervene before death.

A third cause of grave icterus neonatorum is found in certain inflammatory changes in the liver, usually taking the form of an interstitial hepatitis, with which may be conjoined inflammation of the biliary canals. This lesion in the liver is apt to be one of the results of congenital syphilis, as is likewise perihepatitis, which may cause a complete obliteration of the biliary passages. The latter form of inflammation is particularly apt to involve the connective tissue surrounding the common duct, the portal vein, and the hepatic artery on the under surface of the liver. These cases, however, may not always be of syphilitic origin.

---

[1] Diseases of Children, 1886.

D'Espine and Picot report a case in which a jaundiced infant was apparently healthy until the ninth day. At that time there appeared hemorrhages under the skin, at the umbilicus, and in the intestine. The infant became gradually very feeble, and succumbed on the twenty-third day in convulsions. The parents presented no trace of syphilis, and the infant never showed upon its body any appearance of a specific eruption. The autopsy showed a profound change in the hepatic tissue, which appeared to have been the point of departure of all the accidents. The liver was increased in size, and the large biliary canals were permeable. The hepatic tissue, of a greenish-olive color, showed under the microscope an abundant proliferation of young cells in the capsule of Glisson and in the interlobular spaces. This neoformation was continued under the form of elegant garlands around the hepatic cells in the interior of the lobules. The cells were in large part preserved, and contained particles of biliary pigment. The small biliary canals were thickened and filled with epithelial cells: the slight alteration of their lumen permitted the supposition that the lesions they presented were consecutive to the interstitial hepatitis. No gummy points were found. The umbilical vein presented no change. The kidneys were slightly enlarged and very icteric; they presented some disseminated ecchymoses and a cellular proliferation around the arteries which give rise to the vasa recta. The point of departure of all these lesions appears to have been a hypertrophic cirrhosis of the liver with inflammation of the biliary canals.

Diagnosis.—The first point to consider is the diagnosis between true benign icterus neonatorum and false jaundice. In the latter case, the discoloration being due to the remains of a severe cutaneous congestion, there is a yellowish-brown tint usually present, while in true jaundice the color of the skin is more markedly yellow. In true jaundice the conjunctivæ and urine usually present an icteric tint, which is absent in false jaundice. Before deciding upon the actual color of the skin, it may be necessary to employ enough pressure to drive out the blood. The grave form of jaundice may be suspected when the discoloration, instead of disappearing gradually, becomes more and more marked. In the case of congenital defects in the biliary ducts, a slow wasting is conjoined to the jaundice, but without a rise in temperature. The liver and spleen are nearly always increased in size, and there may be at any time a supervention of umbilical hemorrhage. If these latter symptoms are present with atrophy, a malformation of the bile-ducts can be diagnosed although the jaundice be slight or variable. Septic jaundice is recognized by the local symptoms of phlebitis, such as the oozing of discolored pus or blood from the umbilicus, and the symptoms of a general septic poisoning, such as elevated temperature, general sickness and prostration, and possibly a swollen abdomen, that may be very painful on pressure. In cases due to interstitial hepatitis or perihepatitis, besides the local signs referable to the liver, there is apt to be present some trace of congenital syphilis. A careful inquiry into the family history of the father and mother will sometimes throw light on an obscure case.

Prognosis.—Jaundice often causes great alarm in the minds of the laity, possibly from a knowledge of certain fatal cases. It is only necessary to make the distinction by the symptoms in a given case between benign and grave icterus neonatorum in order to be able to give in one case an absolutely good prognosis and in the other an equally bad one. The mere presence of jaundice without other rational or physical signs in a young infant need excite little alarm. I have recently seen a case in which an infant was born jaundiced and remained so continuously for several months. Although the discoloration was deep and well marked, the baby remained plump and healthy, and suffered no inconvenience whatever from this symptom. In cases, however, in which jaundice persists and there begins to be noted an enlargement of the liver, with some wasting, a serious prognosis had better be given. Life is generally most prolonged in the grave form where there is malformation of the ducts. An infant suffering from this lesion may live several months. If umbilical hemorrhage supervenes, death is not long delayed. In umbilical phlebitis with general septicæmia, and in hepatitis, death is usually unavoidable.

Treatment.—The mild form of benign jaundice will often get well without any treatment. In some cases a mild laxative seems to hasten the result. A few tablet triturates of calomel, from a twentieth to a quarter of a grain, given every few hours, often do well. Several grains of gray powder, repeated once or twice, may likewise do good service. Sometimes an alkali, such as bicarbonate of sodium, seems to hasten the disappearance of the jaundice. Two or three grains can be given three times a day. Careful attention must be paid to the digestive organs of the infant. Nursing babies are often put to the breast much too frequently for the good of their digestion. If the nursing be restricted, a teaspoonful of water can be allowed in the intervals. In bottle-fed babies great care must be exercised to dilute and prepare the milk properly, and in many such ways to relieve all digestive disturbances. If there be syphilitic hepatitis, constitutional treatment directed to the specific taint will be indicated. Septic jaundice must be treated by free stimulation and all other measures that can be employed in sepsis. In cases of umbilical hemorrhage applications of strong astringents, such as the perchloride or subsulphate of iron, may be made. If this does not avail, it may be necessary to apply a ligature around two hare-lip pins inserted through the skin at the navel.

JAUNDICE AFTER EARLY INFANCY.

The jaundice that attacks infants some time after birth is due to causes that are similar to those found in children and adults. The bile passes into the blood, owing to some obstruction to its discharge through the biliary canals into the intestine. A catarrhal inflammation of the duodenum, accompanied by swelling of the mucous membrane at the opening of the ductus communis choledochus, may be responsible for the obstruction. The inflammation may extend by continuity from the duodenum to the ductus communis and hepatic ducts and thus cause retention of bile in the liver. There may be causes of obstruction within the ducts that are not due to inflammation. Among these may be mentioned a plug of inspissated bile in the common duct, and, more rarely, gall-stones. Cases have been recorded where a round worm has penetrated the common duct from the duodenum, thus producing complete obstruction. Various inflammatory changes in the liver may produce sufficient pressure to cause obstruction in the intra-hepatic ducts. Thus, the atrophic cirrhosis of the liver sometimes seen in early life may be one of the causes of jaundice. Malarial and miasmatic poisons and phosphorus-poisoning may finally be mentioned as causes of jaundice in children.

Symptoms.—The yellow discoloration of the conjunctivæ and skin is the same as in icterus neonatorum. A symptom often noted is a slow pulse, perhaps forty or fifty beats to the minute, as bile when present in the blood has a sedative effect upon the circulation. The biliary salts are the ingredients of the bile that produce this effect. If there be much slowing of the circulation, the respirations will likewise diminish somewhat in frequency. The most marked symptoms that may be present are those that can be referred to a duodenitis or a gastro-duodenitis. In the latter case there is more or less nausea and vomiting, with pain in the epigastrium, especially upon the ingestion of food, and tenderness upon pressure in this region. There may be a subacute duodenitis without gastritis being present. If so, there is pain and distress when the food passes from the stomach into the duodenum, which usually occurs some hours after the taking of nourishment. Conjoined with this there is tenderness on pressure below the epigastrium at the situation of the duodenum. In these cases a plug of mucus is often found in the common duct where it opens into the duodenum. When jaundice occurs without these inflammatory conditions being present, the nutrition does not for a time appear to suffer, as the appetite may remain good and the digestion of certain articles of food be fairly well accomplished. The fats, however, are digested with difficulty, and the fæcal discharges may contain more or less undigested fat. A careful study of the stools may aid in deciding how complete the obstruction to the passage of bile into the intestine may be. The stools are clay-colored, from an excess of undigested fat, when no bile reaches the intestine. On the other hand, they have somewhat the natural brownish-yellow color when the obstruction to the passage of bile is only partial. One of the known physiological properties of the bile is to act as a sort of natural disinfectant and antiseptic to the contents of the intestinal canal. The complete absence of bile will hence be shown by a quick decomposition of the intestinal contents, as exhibited in the free formation of gases and the foul odor of the fæces when voided. The bowels are generally, but not always, constipated. Itching of the skin may cause great annoyance, especially at night when the skin is warm. Urticaria, which is an exceedingly common affection in children, may occur as an obstinate complication, when the papules and wheals will present a deep-yellow tint. Jaundice may persist for a long time without giving rise to much apparent disturbance, as the system assumes a tolerance of an excess of bile as of other abnormal substances. It may act principally upon the mental powers in the way of producing a sort of stupidity that may be closely allied to somnolency.

Diagnosis.—The principal point to determine in a given case is the pathological cause that has produced it. Evidence of the existence of gastro-duodenitis or duodenitis must first be sought. When there is nausea or vomiting, with pain about the region of the epigastrium, that has preceded and accompanies the jaundice, these conditions may be recognized as causative. If the ducts are inflamed from other causes than a duodenitis, such as a round worm in the common duct, the diagnosis cannot be made during life. If careful palpation reveals a distended gall-bladder, there is positive evidence of obstruction in the common duct.

In cases in which jaundice is merely a symptom of some structural affection of the liver, not only diagnosis but also treatment must be adjusted with reference to the latter lesion. The jaundice is simply one among other symptoms. In many cases, however, a careful examination of the liver will fail to reveal any anatomical lesion to explain the jaundice. We must then fall back on an empirical diagnosis by the mere discoloration of the skin. It is necessary to bear in mind, however, the fact that jaundice may be distinguished from other abnormal tints of the skin simulating it by the yellowish conjunctivæ and by the presence of biliary pigment in the urine. The latter condition is absent in the yellowish-green tint sometimes seen in chlorotic girls, and in any other abnormal discoloration of the skin.

Prognosis.—The prognosis in a given case will, of course, be dependent upon the ascertained cause of the jaundice. Even when the original cause has ceased to operate, some time usually elapses before the discoloration completely disappears. The fluid tissues, such as the blood and urine, are the first to be free of biliary pigment, which remains longer in the solid tissues. As the epidermis is gradually desquamated, the yellow discoloration fades out of the skin. If the jaundice is due to gastro-duodenitis, the prognosis is good, as recovery usually takes place in from two to three weeks. The first indication of removal of the obstruction to the passage of the bile is the appearance of stools that are more normal-looking. If the color becomes darker gradually, it is evidence that the obstruction is disappearing by degrees. If the common duct is occluded by a plug of mucus which is suddenly detached, the fæces will at once be surcharged with bile. A jaundice that persists indefinitely, even where no organic disease can be found, must not be regarded without apprehension. If the general health and strength be good, a jaundice may last for several months without occasioning any special alarm; but cases are sometimes seen where the condition persists for one or two years, and then there are apt to be grave changes in the nutrition of the patient. While the mere accumulation of bile in the system does not appear to produce serious symptoms, the retention of bile in the liver for a certain length of time may produce grave changes in this viscus. The smaller and larger biliary ducts become distended by the pent-up bile, which finally may infiltrate the liver-cells, thus interfering with their function. Sometimes the gall-bladder is distended with bile. The liver is at first increased in size, from its being filled with bile, but finally becomes atrophic. If this process continues, death will finally take place with symptoms of exhaustion or blood-poisoning. Such cases are rare at all ages, and are not so common in children as in adults. Sometimes even mild cases of jaundice may suddenly present evidences of blood-poisoning, which may be followed by death. Fortunately, the majority of cases of jaundice seen in young children disappear in a few weeks without leaving any serious consequences.

Treatment.—The most rational treatment of jaundice is that which is aimed at its cause. As a matter of fact, however, the treatment is often necessarily empirical. Whatever the cause, certain symptoms are usually present that must be alleviated by treatment. Persistent constipation is one of the commonest of these symptoms. In making a choice of laxatives, those which act upon the lower segment of the bowel often do well. Small doses of aloes, rhubarb, or castor oil will fulfil this indication. Drugs which act by irritating the duodenum or the upper part of the small intestine are apt to aggravate the trouble in the common cases of duodenal catarrh. The treatment of jaundice that is most effectual is employed in those cases depending on a subacute inflammation of the stomach and duodenum, and resolves itself into treating the latter conditions. The saline laxatives or mineral waters are best used to cause a suitable action of the bowels when there is catarrh of the duodenum. Karlsbad, Vichy, Congress, and Kissingen waters usually act well. Great care must be exercised in diet, only bland and easily-digested food being allowed. All fatty articles must be restricted, and the patient kept upon lean meat and plain vegetable food. Sometimes counter-irritation in the shape of a small blister at the epigastrium appears to do good.

If there are no marked evidences of gastro-duodenal inflammation, more vigorous means to excite the secreting functions of the intestine and increase peristalsis may be employed. Active peristaltic action in the duodenum may be transmitted to the bile-ducts, and thus a beginning obstruction be overcome. Calomel, rhubarb, aloes, and colocynth may be mentioned in this connection. The action of an emetic, by forcibly compressing the liver and bile-ducts, may free the passages from obstruction. In vigorous children ipecac or a small dose of tartar emetic at the start may prove beneficial. Alkalies, particularly the bicarbonates of sodium and potassium, are supposed to have a liquefying effect upon the bile and thus to free the ducts when they are occluded by a thickening of this secretion. In some cases they appear to have a good effect, whatever may be their mode of action. Tincture of nux vomica may be combined with advantage when one of these salts is prescribed. Nitro-hydrochloric acid is highly recommended by some authorities. Henoch claims good results for it in obstinate catarrhal jaundice.

When jaundice persists and resists ordinary treatment, efforts must be directed to eliminating some of the bile from the system by means of the emunctories. This is to be done by the kidneys and cutaneous glands. The mild vegetable diuretics, the acetate of potassium, and various mineral waters, such as seltzer, have been recommended. Frerichs advises that lemon-juice be given, from one to three ounces daily. He finds that it agrees well with the digestive organs and excites an abundant diuresis. The skin may be kept acting freely by warm baths and by having pure flannels worn to guard against changes of temperature. At the same time, in these prolonged cases everything must be done to support and invigorate the system, so as to obviate as much as possible the depressing effects of the cholæmia.

The first sign of improvement, in case of a favorable issue, will be the disappearance of the biliary coloring-matter from the urine. The real affection has then ceased, although the skin may retain its jaundiced hue for some time longer.

DISEASES OF THE BILIARY DUCTS, ETC.

The affections of the biliary ducts in children practically resolve themselves into an inflammation secondary to a like pathological condition of the gastro-intestinal mucous membrane, as the lining membrane of the duodenum is directly continuous with that of the bile-ducts; also to the occasional wandering of entozoa from the intestine into these ducts. Disease of the ducts produces trouble principally by leading to a retention of the bile, but sometimes the liver-tissue itself may be secondarily involved.

CATARRH OF THE BILIARY DUCTS.

A catarrhal inflammation of the ducts of the liver will present changes similar to those seen in other mucous membranes. One effect often seen as a result of inflammation in this part is a collection of mucus, often taking the form of a firm plug, at the opening of the common duct into the duodenum. This is a frequent cause of the complete obstruction seen in these cases. An ordinary acute catarrh of the biliary ducts usually undergoes complete resolution in a few weeks without any bad results being left behind. If the inflammation becomes chronic, certain secondary lesions may develop. A thickening of the ducts, with dilatation in places, caused by the obstructed secretion, may result. Rarely, ulceration may take place in the walls of the ducts. The mucous membrane of the gall-bladder may be the seat of catarrhal inflammation and the ducts not be involved. This takes place from thickening and alteration of bile that has remained for a long time stagnant in the gall-bladder.

Etiology.—Since in the large majority of cases the inflammation spreads by direct continuity from the duodenum into the common duct, the causes producing irritation of the former structure must be considered in this connection. Acute indigestion produced by overloading the stomach with all kinds of improper food and drink will stand as the commonest cause. Certain infectious diseases, and acute or chronic malarial attacks, may cause enough gastro-duodenal irritation to provoke an actual catarrhal inflammation. These affections may likewise act as causes of catarrh of the biliary passages by inducing a hyperæmic condition of the liver which is shared in by the ducts.

Symptoms.—The disease is apt to begin with various digestive disturbances, shown by a coated tongue, nausea or vomiting, and a disinclination to take food. There may be a slight fever and other symptoms pointing to a mild catarrh of the stomach. In a few days the conjunctivæ begin to be tinged with yellow and the urine is colored by biliary pigment. Soon a marked jaundice develops, and the fæces lose color, assuming the well-known clay-like appearance. There is often a slight enlargement of the liver, which projects a little below the ribs, and the gall-bladder may likewise be felt projecting below the margin of the liver, assuming a sort of pear-shape. The jaundice accompanying this affection generally lasts two or three weeks, although it may not disappear for two or three months when the inflammation of the duodenum and bile-ducts is severe or chronic. At first there is tenderness on pressure over the epigastrium and the right hypochondrium. When the inflammation of the ducts is secondary to congestive changes in the hepatic tissue, there is less digestive disturbance, and the jaundice is not only fainter in degree, but is also not apt to last so long. Its duration will, of course, depend upon the nature of the original hepatic disturbance. If the gall-bladder alone is the seat of catarrhal inflammation, there will be no jaundice, and the symptoms in general will be very indistinct. The gall-bladder may sometimes be mapped out as a pyriform swelling, which may be the seat of a dull pain.

Diagnosis.—The diagnosis consists in recognizing the existence of a gastro-duodenal catarrh, or, after eliminating this, in carefully seeking for some affection of the parenchyma of the liver that may induce a catarrhal inflammation of the biliary ducts.

Treatment.—The treatment is essentially the same as that recommended for ordinary jaundice in children.

ROUND WORMS IN THE BILE-DUCTS.

It happens very rarely that round worms find their way into the biliary ducts and produce grave or fatal symptoms. When we consider the active movements of this worm and its tendency to invade different cavities, the wonder is that the biliary passages are not oftener invaded. Although the worm enters by the common duct, it is usually found in the gall-bladder or one of the branches of the hepatic duct. Cases have been recorded where a worm has been found partly within the common duct and partly in the duodenum. Several worms may be present in the ducts, and they may cause inflammation, with obstruction or dilatation of the passages. Occasionally ulceration may result. Frerichs mentions a case reported by Lieutaud where a boy of fourteen years was attacked with fever and painful distention of the epigastrium and of the region of the liver, with salivation and jaundice ; the stools lost their color, the pulse became intermittent, and death took place in convulsions. At the autopsy the liver was found to be yellow and enlarged ; the gall-bladder was distended with bile, and the common duct was blocked up by a good-sized round worm, while large numbers of similar worms were found in the stomach and intestinal canal. The symptoms in these cases are too obscure to warrant a diagnosis. There may be acute pain in the epigastrium, with vomiting, and finally convulsions, from reflex irritation of the filaments of the hepatic plexus. As the diagnosis is uncertain, the treatment must be directed to symptoms.

INFLAMMATION OF THE PORTAL VEIN.

Suppurative pylephlebitis only will be considered, as the adhesive variety occurs very rarely, if ever, in early life. The former variety occurs as a secondary lesion, resulting from suppuration in some of the organs drained by the portal vein or its radicles. Ulcerations of the gastro-intestinal mucous membrane, resulting from inflammation induced by various foreign bodies or by hard masses of impacted fæcal matter, may be recognized as a not unusual cause. Pylephlebitis may be secondary to inflammation or ulceration of the biliary ducts. Typhlitis or perityphlitis or chronic peritonitis may likewise give rise to suppuration within the portal vein. Umbilical phlebitis in new-born infants whose mothers are septic may spread to the portal system and set up inflammation there.

Symptoms.—The symptoms of the primary morbid condition are usually to be noted before the signs of inflammation in the vein itself.

Pain in that part of the portal vein or its branches which is involved in the inflammation is the first local sign of disturbance. This is followed by enlargement of the liver and spleen, which become tender on pressure. The pain in the liver may be due to a general hepatitis or to the formation of abscesses in this organ. A complete occlusion of the splenic vein leads to considerable swelling of the spleen and to pain in the left side. As pus forms in the portal vein, there will be chills, fever, sweating, and other hectic symptoms. The patient rapidly emaciates, and exhibits such typhoid symptoms as low delirium and somnolence. Sometimes before there are such evidences of blood-poisoning there may be vomiting, swelling of the abdomen, which becomes extremely painful, and other signs of a general peritonitis. In many cases there is diarrhœa, with bilious stools that may contain a little blood. Jaundice develops during some part of the progress of the disease in a majority of the cases. The skin and urine may be only slightly colored, however. There may be some remission in the severity of the symptoms, but the disease generally reaches a fatal termination in a few weeks.

Diagnosis.—It is difficult, if not impossible, to make an early diagnosis, from the obscurity of the symptoms. Attention may first be directed to some local inflammation and suppuration in the course of the portal vein. If, following this, there is severe pain somewhere in the course of the vein, with rigors and sweating, more or less marked jaundice, enlargement of the liver and spleen, bilious stools, and rapid failure of the vital powers, the diagnosis of portal pylephlebitis can pretty certainly be made. It must be remembered that the symptoms may finally resolve themselves into blood-poisoning and general peritonitis.

Prognosis.—The prognosis is always fatal, unless only a small radicle of the portal vein is involved in the inflammation.

Treatment.—All that can be done in the way of treatment is to make the patient as comfortable as possible and to treat symptoms as they arise. The pain and diarrhœa may be relieved by opiates, and the general strength sustained as long as possible by the use of a nutritious diet and stimulants.

LITHÆMIA.

Children frequently suffer from a functional disturbance of the liver that gives rise to various digestive and nervous symptoms. These are similar to those seen in adults affected with lithæmia, and the principal objective evidence of faulty nutrition will be found in the urine. The tongue is coated and the breath offensive. Constipation is usually present, and the stools are pasty and lacking in bile. There is an unhealthy appetite, sometimes abnormally large, and the children have a pale, sallow appearance. Complaint is commonly made of headache. Young children become extremely fretful when suffering from this affection. They wish to urinate frequently, and a reddish-pink sediment of urates is deposited in the chamber. Anæmic girls are very apt to become lithæmic before or at the time that they begin to menstruate.

Treatment.—The first object of treatment is to get the bowels acting regularly. A few small doses of calomel may be first given, followed by fluid extract of cascara sagrada or aloes. Nux vomica combined with an alkali, such as bicarbonate of potassium, or an acid, such as dilute hydrochloric acid, may then be administered. Good effects will often be had by changing from an acid to an alkali, or *vice versa*. The child's diet should be carefully regulated. Too much meat, as well as an excess of starchy food, must be avoided. Pastry and sweets must all be cut off. Plenty of out-door exercise, well-ventilated rooms, salt baths with friction of the skin, and all kinds of beneficial hygienic measures to improve the general health, may be employed with advantage.

ENLARGEMENTS OF THE LIVER:

THE LIVER OF CHILDREN; AFFECTIONS WHICH SIMULATE ENLARGEMENT OF THE LIVER; CONGESTION OF THE LIVER; FATTY INFILTRATION; AMYLOID DISEASE; HYDATID DISEASE; ABSCESS; TUMORS OF THE LIVER.

By J. H. MUSSER, M.D.

Affections of the liver occurring in childhood have received but little notice from systematic writers on the diseases of this period of life. The literature of the various diseases, therefore, is quite scanty.

The reason for this is obvious. The liver plays an important physiological part in the growth and development of childhood, but, fortunately, is not often the seat of pathological changes during that period. When one recalls the etiology of liver-diseases, this is readily understood. Practically, all affections of the liver occurring in adult life are due to habits (sedentary, gall-stones), and to errors in diet (fatty liver, congestions, cirrhosis, singly or combined), or occur secondarily to some grave cachexia or some form of disease in distant organs. These causal processes operate over long periods of time, and therefore either they are rarely operative in childhood, or sufficient time does not elapse for the pathological changes to take place. Hydatid disease, in countries where it prevails, occurs more frequently than any of the other grave affections, and is the only exception to the statement just made.

As the various affections of the liver are rare, it does not fall to the lot of one man to see many of them, and hence the writers on diseases of children were loath in the past to discuss the subject. A similar hesitancy has existed until within a short time. The growth of population and the increase of special hospitals for children have, however, made it more practicable for single observations to be made. The accumulated results of the more careful observations scattered through the literature of medicine form sufficient data for intelligent writing on any diseases of the liver incident to—or, rather, occurring in—childhood. This literature is rendered accessible by the growth of libraries and the perfect system of cataloguing of the Library of the Surgeon-General's Office at Washington. Without the advantages one derives from this institution it would be an herculean task to perform thorough literary work. To the marvellous growth of literature and the readiness of access to it, the writer is indebted for any degree of completeness that this essay may possess. The works on diseases of children which have been consulted are given in the foot-note on this page.[1] In addition, special articles were consulted, reference to which will be found after each individual section.

The lack of an exact pathology, and a want of harmony in the nomenclature of hepatic diseases, have also been great obstacles to the growth of any accurate knowledge of hepatic diseases. Hence much confusion has existed in the past on this account.

The most frequent diseases of the liver that occur in childhood cause enlargement of that organ. The importance relatively of this portion of the subject, therefore, calls for a rather extended notice of the various diseases of this character, as well as for preliminary remarks on the size of the liver and its anatomical relations in childhood, especially as there are some differences in this period of life from the liver of adult life. After the introductory remarks, the various affections which may simulate an enlargement of the liver—or, as Murchison states it, may cause spurious enlargement of the organ—will be treated of. Finally, the affections of the liver causing enlargement will be detailed in systematic order.

THE LIVER OF CHILDREN.

In another portion of this work the relative proportion of the weight of the liver to the weight of the entire body during the various periods of life, as well as a statement regarding its size, is given. This is constantly referred to by writers, and it shows that the liver of a child is much larger relatively than the liver of an adult. The increased size is particularly seen in the left lobe, although there is uniform enlargement of the right lobe. The functions of the liver in fœtal life call for this enlargement, its meaning is well understood, and it is explained in another portion of this section. The following table, taken from Birch-Hirschfeld, gives the percentage of weight of the liver in infants and children relative to the whole body-weight. It indicates in another form the statement made above.

Vogel says that the liver of a new-born child weighs, on an average, one hundred grammes, but that of a child sixteen months old two hundred and fifty grammes, so that there is no actual diminution in weight of this organ after birth.

The size and shape of the liver are ascertained during life by palpation, inspection, and percussion. In health on inspection the right side does not materially differ from the left, and in childhood only do we learn of the normal liver and its position by an unwonted fulness in the epigastrium. This is most marked when the child is the subject of a wasting disease which does not cause any change in the size of the liver. Such fulness, with increased dulness on percussion, as will be indicated, has been taken, as the writer has seen, for an abnormal swelling or tumor. In children sometimes on palpation the border of the liver, which in health is an inch below the margin of the ribs, can be detected. The difficulty in feeling the edge is due to the usually tense and fully-distended abdomen of childhood. By inspection aided by palpation, movement of the liver can often be discerned. It is to be remembered, as an important diagnostic point, that the liver descends on normal or full inspiration and ascends in expiration, on account of the action of the diaphragm.

It is by percussion, however, that we most accurately define the borders of the liver, and hence its size and shape. By this means in the right mammary line the upper border of the liver-dulness is found to begin in the fifth interspace; at the right sternal border, in the same interspace; in the axillary line, at the seventh rib; and in the mid-scapular line, at the ninth rib. This represents the uppermost limit of the liver-dulness on strong percussion, while the superficial line of dulness on light percussion would begin half an inch to an inch below the position indicated. In the median line of the sternum the upper border of the left lobe begins at the articulation of the xiphoid cartilage and extends to within an inch of the umbilicus. The upper border of the left lobe cannot well be distinguished, because of the continuance of cardiac and hepatic dulness in this region. As indicated when speaking of palpation, the lower border of dulness of the right lobe extends below the margin of the ribs. Very frequently this is difficult to determine in children, on account of the flatulent abdomen. It can be determined accurately only by light percussion, while the opposite degree of force is necessary to develop the upper line of hepatic dulness. It is to be remembered that the line of dulness of the upper border is arched, the highest point being in the middle of the axilla.

An enlargement of the liver is ascertained by the above-noted methods, and the nature of the enlargement is inferred by their means, as well as by the use of the aspirating-needle, by which enlargements due to solid growths are distinguished from enlargements caused by fluids.

When the right lobe is enlarged, on inspection the lower portion of the thorax on that side is seen to be much more distended than the corresponding portion of the left side, while if the left lobe is involved the epigastrium is full and swollen. The lower border of the liver can often be seen, but its limits may be accurately defined only by palpation.

By percussion enlargement of the liver is detected, and by the same means it is determined whether the enlargement is uniform or is more marked in one particular direction. Thus, the enlargement may be chiefly upward, extending as high as the third or even the second rib. A cyst on the convex surface, or an abscess in this position in the right lobe, or a new formation, may cause an increase upward. Under such circumstances the respiration, of course, is much interfered with, and hence there is more movement of the unaffected side. Increase of dulness downward is found when there is a uniform enlargement of the organ, as in the fatty or amyloid liver, when neoplasms are situated along or near the lower border of the liver, and when a hydatid cyst develops within the body of the liver. In these affections the upper border is not usually changed, except in amyloid disease.

Irregular enlargement is generally due to a hydatid cyst, and under such circumstances the dulness is either directly upward or directly downward. As pointed out by Ward,[1] it is important to remember that enlargements of the liver, however much they may extend beyond, chiefly occupy the normal site of the organ, and that the usual outline of the liver may be traced. Moreover, such enlargements follow the movements of the diaphragm in full respiration chiefly.

---

AFFECTIONS WHICH SIMULATE ENLARGEMENT OF THE LIVER.

Congenital malformation of the liver, and disease of the structures or organs within the thorax or abdomen adjacent to the liver, frequently simulate enlargement of that organ. Murchison and Frerichs particularly call attention to a large number of such conditions, and other systematic writers dwell upon the subject as seen in adult life. Many similar conditions obtain in childhood, some of which will be referred to.

1. **Congenital Malformations.**—Unusual changes in form of the liver, sometimes found at birth, are such as to simulate enlargement of the whole organ. This is seen particularly when the liver has assumed a quadrangular or rounded shape, the area of dulness being increased very much in a vertical direction. Birch-Hirschfeld refers to a case observed by him of enormous enlargement of the liver, symmetrical in form, so that the left lobe corresponded to the right in form and size, on account of congenital absence of the spleen. Such abnormal development must be remembered, and is spoken of here for convenience, as it simulates an enlargement. In cases of congenital diaphragmatic hernia the liver may be found in the right pleural sac, and hence simulate an enlargement upward. Congenital malformations which simulate enlargement may be suspected in the absence of any symptoms of hepatic disease, in the absence of any conditions which may cause other forms of spurious enlargement, and where the increased dulness has existed from early life.

2. **Rickets.**—In rickets the shape of the chest may cause the liver to assume such a position that its area of dulness may be increased and its edges be felt far below the margin of the ribs. Moreover, transverse compression of the liver by the ribs is likely to cause a depression of its surface and elongation of the viscus in the vertical direction.

Disease of the vertebræ often leads to such transposition of the thoracic and abdominal organs as to make it almost impossible to locate them exactly. The normal seat of the liver is often changed, and enlargement may be simulated.

Pseudo-enlargement of the liver must not be confounded with the enlargement which some writers hold to be actually present in cases of rachitis. Jenner, Dickinson, Parry, and others, in their masterly articles, lay great stress upon enlargement of the liver in rickets. Cheadle[1] does not believe that enlargement is caused by this affection; while Fagge, Goodhart, and Gee regard any enlargement which may be present as a result of previous cachexia, apart from rickets. The first writer thinks the enlargements that occur are found only in those forms which are modified by syphilis. He does not consider the matter settled by any means.

3. **Chest-Diseases.**—In children enlargement of the liver may be simu-

lated by pleural effusions or pneumothorax of the right side, and by pericardial effusions which push the liver downward.

Pleural effusions are more likely to be taken for enlargement of the liver because they often develop latently and without symptoms referable to the lungs. The difficulty in distinguishing a pleural effusion from an enlargement of the liver is great, because the dulness of each is continuous. To guide us in the detection of a pleural effusion the following physical signs may be of service. In a pleural effusion there is uniform bulging of the side. The upper border of dulness of an effusion, if not too large, may be movable. The line of dulness is S-shaped (Garland) if the effusion is small, and horizontal if it reaches two inches above the nipple (Gee). The liver does not ascend and descend synchronously with the respiratory movements, in cases of pleural effusion. Finally, the upper line of dulness of a pleural effusion changes with the position of the patient.

Hepatic enlargement causes eversion of the lower costal cartilages, which is not seen in pleural effusions. A depression may be seen between the lower margin of the ribs and the upper surface of the liver when that organ is pushed down by a large pleural effusion. The use of the aspirator is often necessary to distinguish between the two conditions.

The well-known physical signs of pneumothorax serve to distinguish that affection. In emphysema of the lungs the liver may be displaced downward. In childhood the rickety chest, and the transverse groove which frequently accompanies emphysema, give physical signs which appear to indicate an enlarged liver.

The rational symptoms of dyspnœa, of cough, and of chest-pain are distinguishing features of the thoracic diseases just indicated.

The physical signs of pericardial effusion and of dilated heart are sufficiently well known to require reference only. Of course, to distinguish true enlargement of the liver from the affections just indicated one must weigh the history of the case and the origin and mode of development of the disease, as well as consider the rational symptoms and physical signs.

Hydatid disease and abscess of the liver are frequently complicated by the presence of an effusion in the pleura, either serous in character or containing pus. Frequently the liver-affection had not been thought of, and hence when an empyema or a pleural effusion is detected the condition of the liver must be inquired into. The mode of onset of the disease, and the presence or absence of disease of other organs, as heart-disease or renal disease, which might cause an effusion, must be considered. The tendency of an empyema to become localized and cause a swelling which may appear to be connected with the liver must be remembered.

4. **A collection of fluid** between the upper surface of the liver and the diaphragm may simulate enlargement of the liver. The liver is pushed downward, and hence the area of dulness is increased in that direction. Abscesses and encysted collections of serous fluid between the liver and the diaphragm have been described by many authorities. Murchison details

an interesting example of this condition in a boy aged ten years, in whom, after an attack of scarlet fever, a tumor was found below the right ribs, which increased in size without causing any pain. The globular tumor in the right hypochondrium extended three inches below the level of the umbilicus. It measured six inches over its convexity vertically, and six and one-half inches transversely, and the circumference at its base was fourteen inches. The cartilages of the lower right ribs were slightly everted, and the girth here was one-fourth inch more than on the left side. The tumor was painless, and distinctly fluctuating throughout, and there was no induration at its base. The light of the sun or of a candle was distinctly transmitted through it. When the patient coughed, an impulse was conveyed to the tumor, and when he lay on his back a portion of the tumor seemed to disappear beneath the ribs. The tumor was also largest when he sat up. There was clear vesicular breathing at the base of the lungs, which descended to the normal level both anteriorly and posteriorly. The lower edge of the liver could not be felt through the tumor, which descended slightly on the patient's taking a deep inspiration. There was tympanitic percussion noted between the tumor and the right kidney. The boy's general health was good.

The tumor was aspirated four times, and sero-pus withdrawn. After the fourth puncture the tumor opened spontaneously, and from it a clear viscid fluid continued to discharge for one month. A probe could be passed through the opening inward and downward and outward beneath the abdominal wall to the extent of an inch and a half, but upward beneath the ribs and above the liver to fully three inches.

Bright records a case of large abscess between the diaphragm and the liver, which produced apparent enlargement of the liver. To determine the actual presence of serum or pus in this region, aspiration, of course, is necessary, and, indeed, unless it is performed a diagnosis cannot well be made.

5. **Affections of the abdominal viscera** may cause spurious enlargement of the liver. Under these circumstances the liver is pushed upward and the enlargement is noted in that direction. In cases of ascites, either general or localized in the right hypochondriac region, an apparent enlargement is often seen. When the abdominal cavity is filled with fluid, so that the dulness is continuous with liver dulness, the exact position of the liver can often be determined by having the patient lie on the left side. The general increase of dulness over the abdomen would put one on his guard; but a collection of fluid is often confined by adhesions to one portion of the abdomen, as the right side, and, its dulness being continuous with the hepatic dulness, to distinguish it is very difficult. The occurrence of fluctuation may aid, while the change of the normal outline of the liver and the absence of movement on inspiration, with a history of peritonitis, especially the tubercular form, would indicate an encysted collection of fluid.

Tumors of the ovary, the uterus, or the omentum in children rarely, if ever, cause an apparent enlargement of the liver by growing upward in apposition to it. Tumors of the right kidney—sarcoma, encephaloid cancer, and cystic disease of that organ—may grow upward in contact with the surface of the liver and cause an increased area of dulness continuous with that of the liver. Moreover, by palpation the edge of the liver cannot well be distinguished. Murchison thinks the fingers can usually be inserted between the ribs and the upper part of the renal tumor. Others affirm that a clear space on percussion over a renal tumor, indicating the presence of the large intestine, can be found. The renal tumor, moreover, does not ascend and descend with the respiratory movements; it partakes somewhat of the shape of the kidney, and is rounded on every side (Jenner).

Accumulation of fæces in the transverse colon in adults is a condition difficult to distinguish from enlargement of the liver. In children such accumulation occurs very rarely, and can possibly be detected—or, rather, suspected—by its association with constipation and with spasmodic colicky pains, if the bowels are obstructed. Of course the well-known rule, that the nature or character of a tumor within the abdomen should not be pronounced upon until a purgative has been administered, holds good with tumors in childhood.

6. Some **inflammations of the abdominal walls** may cause a tumor which can be told with difficulty from one due to an inflammatory enlargement of the liver. Frequently in childhood an abscess in the walls of the abdomen, in the epigastric or the right hypochondriac region, develops slowly and exhibits signs not unlike those of an abscess of the liver. Percussion cannot well define the area, on account of the tenderness and pain; the inflamed area is more tense and fixed than a similar area connected with the liver. In these latent abscesses the constitutional symptoms are less marked than in abscess of the liver.

The writer saw a case of a child two years old with an acute cellulitis, with suppuration, in the hepatic region, which prevented the usual examination of the liver from being made, and hence permitted of the surmise that the abscess originated in the liver. The immediate superficial inflammation, without antecedent local or general symptoms of hepatic origin, characterized the abscess in the abdominal walls.

Murchison calls attention to the rare occurrence of phantom tumors of the abdomen in childhood which may simulate an enlarged liver and most frequently a hydatid of the liver. A girl eleven years of age, of healthy appearance, presented, two years prior to consulting him, a tumor in the epigastrium, which increased for a year and since then had been stationary. She had some dyspepsia, but no pain. A prominent rounded swelling extending from the lower end of the sternum to below the umbilicus was found, and appeared to be due to contraction of the recti muscles. It was for the most part dull on percussion. Its surface was smooth and elastic, but not fluctuating. Over the ensiform cartilage the slightest pressure caused pain. The size of the bulging varied slightly according as the patient's attention was or was not directed to it. Under anæsthesia the tumor disappeared entirely, but it returned when the effects of the chloroform passed off. Under constitutional treatment for a long time, it gradually diminished, and years afterwards the patient was in excellent health.

CONGESTION OF THE LIVER.

Congestion of the liver may be active or passive. Active congestion, or hyperæmia, is seen physiologically after eating. It may become pathological through irritation of the mucous membrane of the stomach by stimulating articles of food. It occurs in the first stage of an abscess of the liver, and in the course of many infectious diseases. Under the influence of high temperature and of malaria, enlargement from congestion is said to take place. Of the infectious diseases, scarlet fever, typhus, and cholera are the most frequent causes.

Passive hyperæmia is a secondary affection, and is caused by anything which hinders the outflow of blood into the ascending vena cava. Heart-disease and diseases which interfere with the pulmonary circulation are the most frequent causes, a stasis of blood in the liver being produced.

Billard says he has seen in the asphyxia of the new-born a congestion so great as to cause a bloody exudation on the surface of the liver, and even an effusion of blood therefrom.

Morbid Anatomy.—In active congestion the liver is enlarged, the capsule tense, and its surface red. On section, bright red blood oozes abundantly from the cut surface, and the vessels are distended. The central veins of the acini are not distinct,—indeed, may be seen with difficulty,—on account of the fulness of the other vessels and the pressure upon the central vein by the crowded cells. The structure of the liver is firmer than in health, until a considerable oozing of blood takes place. The hyperæmia is uniform throughout the liver, except when it precedes the formation of an abscess, in which case it is localized, and in some cases of abscess of the liver one sees different areas of hyperæmia which are doubtless the first stages of a commencing abscess.

The liver of passive hyperæmia is much enlarged,—more so than in the enlargement of active congestion; its surface is often irregular; the capsule is dull, and often inflamed in defined areas. The liver is firm on pressure and grits on section. Its color is dark red, and dark blood oozes from the cut surface. The central veins are enlarged and dark, and are surrounded by a zone of gray or yellowish color. The well-known nutmeg-appearance is thus produced. There is frequently an overgrowth of connective tissue which causes the firm structure of the liver. Often the organ is twice or three times its normal size. Generally there is some obstruction of the outflow of bile, and the mucous membrane of the ducts is swollen and congested.

Symptoms.—Active congestion of the liver is said to be accompanied with sthenic constitutional, and pronounced local, symptoms. A chill, followed by fever which rises to 104° F., with gastric disturbance, headache, mild delirium, and occasionally convulsions, may occur, apart from hepatic symptoms. Locally, in addition to increase in the size of the liver, the hepatic region is the seat of pain, and of tenderness on pressure. The child lies on the affected side, with the limbs drawn up. Vomiting is a quite common symptom, and is often most obstinate. It is not necessarily bilious. The fever abates at the end of forty-eight hours, but the pain and tenderness continue. The general symptoms are relieved and the local ones ameliorated by free action of the bowels and by free perspiration. We are not familiar with the state of the urine during an attack of active congestion of the liver.

The symptoms just indicated are so marked and are so indicative of local inflammation that I fear most cases of active congestion of the liver are really cases of perihepatitis. This is all the more likely if the attacks occur in a syphilitic or in a tubercular subject.

The symptoms of passive hyperæmia of the liver are twofold, and are due, first, to the cause of the passive hyperæmia (affections of the heart or lungs), and, second, to the enlarged liver and the mechanical effects of such enlargement. The first class of symptoms need not be described.

Of the second class, uniform increase in the area of dulness of the liver is found. On palpation, the edges of the liver can be felt, smooth and rounded, as far down as the umbilicus in the median line, and almost to the ilium in the nipple-line. The enlarged liver may cause marked enlargement of the lower part of the thorax and the upper half of the abdomen. With the enlargement of the liver, the spleen is likewise increased in size; the upper half of the abdomen is distended and its surface regular. Abdominal distention becomes very great when ascites takes place. It is impossible to tell whether the ascites is due to the primary lesion or to the secondary change in the liver. After the development of ascites, and possibly from the same cause,—that is, contraction of the liver,—the external abdominal veins may become much enlarged.

In the course of pulmonary disease, and in cardiac disease when failure of compensation occurs, the liver becomes the seat of passive congestion. In addition to the indications shown by the heart and lungs and the physical signs of enlargement of the liver, gastro-intestinal symptoms arise. These symptoms are due to secondary congestion of the mucous membrane of the alimentary tract. The tongue becomes furred, the appetite is lost, vomiting may or may not occur, flatulent dyspepsia is marked, and the well-known symptoms of intestinal dyspepsia arise. The bowels are irregular, and in the later stages the stools are light in color and show the absence of bile.

With the onset of the enlargement the face is said to become more sallow, and frequently the conjunctivæ are tinged yellow, while a general jaundice may supervene. Of course, if the duration is sufficiently prolonged, as is usually the case, the symptoms of gastro-intestinal catarrh may arise and hemorrhages from the stomach or bowels take place. Jacobi refers to the frequent absence of symptoms of chronic hyperæmia except short and troublesome breathing after meals or exertion. A dirty-greenish, pale hue of the skin, and the almost œdematous puffiness around the eyes, are seldom wanting. He refers to the observations of Battersby, who calls attention to the condition of the mucous membrane of the stomach by which a morbid over-secretion leads to a voracious appetite known as "pica." The latter writer, quoted extensively by Churchill and many others, observed sixteen cases; and five out of eleven died. The age varied from under one year to seven years. The symptoms do not indicate chronic hepatic congestion, as it is understood at the present day. All the authors who quote Battersby refer to the depraved appetite, observed in seven cases. Cheyne mentions a family in which eleven children died of jaundice associated with enlarged and congested liver. On account of the more accurate pathological knowledge of the present day, clinicians do not lay as much stress on hyperæmia of the liver as they did formerly.

Diagnosis.—Active congestion of the liver is of short duration, and is not likely to be confounded with any other hepatic affection. It must not be confounded with acute gastritis or with perihepatitis. Passive congestion of the liver can be recognized by the association of enlargement of that organ with the evidence of cardiac dilatation commonly secondary to disease at the mitral valve, the usual heart-lesion of childhood.

It may, of course, be confounded with amyloid disease of the liver, the characters of which will be pointed out when treating of that division of our subject. Hypertrophic cirrhosis of the liver presents the same uniform enlargement as passive hyperæmia; but the usual presence of jaundice and of ascites early in the history of the case, with the absence of disease of the central organs of circulation, indicates the existence of the former disease. Moreover, the mode of development of passive congestion, the physical characters of the liver, and the occurrence of venous engorgement of other organs, render easy its distinction from hypertrophic cirrhosis.

The enlarged liver of passive hyperæmia is of the same character as the liver of leukæmia, an affection which may possibly arise in the course of cardiac diseases. The symptoms of cirrhosis of the liver due to syphilis and enlargement of the organ from that disease simulate those of passive congestion of the liver. But the perihepatitis of the syphilitic liver causes pain, which is absent in passive congestion.

It is to be remembered that the liver of passive congestion may diminish in size, and, if compensation is secured in the heart, the gradual return of cardiac tone may be such as to relieve the venous engorgements. Pathological changes in the liver may arise and a form of cirrhosis develop. The liver becomes reduced in size, and has all the characteristics of cirrhosis. Under such circumstances it is difficult to distinguish this form of cirrhosis from the other forms, or from the syphilitic liver.

Prognosis.—The prognosis of active congestion of the liver is good.

Repeated attacks may lead to chronic engorgement, with the establishment of cirrhosis, in the varieties due to intemperance in food and drink; or to grave organic disease. Such attacks in warm climates may induce an abscess of the liver.

The prognosis of passive hyperæmia of the liver depends upon the ability of the heart to regain its lost strength and upon the duration of the disease, as well as upon the presence or absence of an individual tendency —which, no doubt, is seen in some cases more than in others, but cannot be estimated—to an overgrowth of connective tissue. The enlarged liver of passive hyperæmia may, after being under observation for months, return to the normal size and not be followed by cirrhosis. The following case is one of passive congestion of the liver without any cause that may account for it. For this peculiarity the case is worthy of record.

Tumor of the Liver, Lesions analogous to those of the Cardiac Liver without Disease of the Heart.[1]—A girl six and a half years old presented herself, April 6, with an enormous development of the belly. Palpation, in spite of the ascites, which seemed considerable, disclosed the fact that the liver was very large and descended to more than a hand's breadth below the false ribs and to some centimetres above the right iliac spine. The subcutaneous veins of the chest and of the abdomen were strongly distended, and marked the obstruction of the portal circulation. There was no œdema of the lower limbs. The general condition was excellent. The patient had a good appearance,—rosy color, no trace of jaundice; she ate well, did not vomit, and had no pain.

No antecedent syphilis was found in the parents, who said that the child had never been sick, and that the rapid development of its belly had begun only two or three months before; however, for a long time it had had a slightly prominent abdomen.

The patient was received in the service of M. Archambault. Examination showed ascites; sharp border of liver felt below umbilicus; on anterior surface, the consistency of which seemed a little firm, no bosses could be found. Difficult to tell whether fluctuation existed or not, for the liver was movable in the ascitic liquid and was displaced by the least pressure.

Urine dark, but containing no more urates than in normal condition. Heart apparently normal; patient never had hemorrhage.

April 8. Puncture of abdomen, to relieve tension and permit a more complete examination of liver. Good-sized trocar used, but only two or three drops of liquid obtained. A second puncture, by M. Rathery, with no more satisfactory result. Fluid obtained had all the characteristics of ascitic fluid. The perfect health of the child led to the opinion that there was a hydatid cyst with ascites by compression.

April 9. Liquid steadily flowed from puncture and infiltrated cellular tissue of abdominal walls. Pressure at the ribs a little painful, but no redness and no heat of the skin. Belly much less distended, no inequalities in the liver, tissue loose, but no fluctuation. Exploratory puncture of the liver at about four centimetres below the ribs, in the middle of the right hypochondrium. No result, and no accident following it.

April 12. Ascitic liquid escapes by the fistulous passages. Skin around them red and hot; infiltrated parts begin to be inflamed. Tongue a little dry, slight fever appears. M. Sabric thinks there is a hyatid cyst, and recommends a new puncture.

April 15. Two exploratory punctures some centimetres below the first; not a drop of liquid escapes. No accident during the day.

April 17. Inflammation around fistulæ still very acute, belly more tense, violent fever, and vomiting during the day.

April 19. The acute symptoms were due to a phlegmonous erysipelas about the fistulæ, for, as regards the liver, the belly is not painful, there is no tympanites and no peritonitis.

---

[1] Savard, Bull. de la Soc. Anat., 1880, lv. 291.

April 20. Erysipelas extends to the middle of the back, ecchymoses appear near the groin on the same side; vomiting ceases, replaced by hiccough. Patient sinks into collapse; no longer recognizes its parents. Towards three o'clock the extremities became cold, and death occurred at four.

Autopsy.—About three pints of transparent liquid in the abdominal cavity. No adhesions of intestines and no trace of peritonitis. Trace of punctures distinctly seen on peritoneum; Savard cannot explain why liquid was not freely evacuated; trocar penetrated perfectly into serous cavity. No hydatid cyst.

Liver at least double its normal size, of a sombre red color. On section, consistency a little firm, in spots a little jaundiced in color. Subhepatic veins much dilated and contain some large clots, pretty hard, which on section and superficial examination seem to have small lardaceous nuclei. No clots in portal vein, outside the liver, nor in the vena cava.

Microscopic examination shows that the lesions resemble those of cardiac liver. Hepatic cells deformed, flattened, and nearly completely atrophied by the enormous development and distention of the venous channels and capillaries; they are slightly pigmented. These vascular dilatations form the largest part of the mass of the liver; they are filled by blood-globules of exact contour.

Treatment.—Theoretically, active congestion of the liver should be treated by means of local depletion. Of course the cause must be removed if possible, and the diet carefully selected to prevent a recurrence. Alcoholic liquors, spices, fat, and rich articles of food must be interdicted. Local depletion by means of cups or leeches over the surface of the liver yields prompt relief; in milder cases mustard plasters may be used; and after such local depletion light flaxseed poultices or a hot-water bag must be applied. Purgatives should be administered,—preferably the salines, which deplete the portal circulation. Phosphate of sodium in small and repeated doses, effervescing draughts of citrate of magnesium, or Rochelle salt may be prescribed.

Of remedial agents the chloride of ammonium is the best. It may be given in doses of from three to five grains every two hours until relief is obtained. Ipecacuanha in small doses is believed to increase the secretions of the liver, as well as to produce an action of the skin, and it may be used in this disease. Anodynes are not to be used, but relief is to be secured, if possible, by the use of the local means and a general warm bath or hot bath.

The treatment of passive congestion of the liver is divided into, first, the treatment of the heart, and, second, the relief of temporary local symptoms. Thus, weight and tension are relieved by means of purgatives. The tendency to sclerosis, which is possible in all cases in which the cardiac force has been renewed, may be counteracted by hygienic and dietetic means. The bowels must be regulated by salines. All forms of food liable to stimulate the portal circulation should be prohibited, and for a long period a diet which scarcely disturbs hepatic functions must be used.

FATTY LIVER.

Etiology.—The fatty liver includes fatty infiltration and fatty degeneration of the organ, first described by the older writers. By infiltration is meant the deposition of fat in the tissues. When applied to the liver, the condition may not be truly pathological. In children with active digestion who exercise but little and whose respiration is not vigorous, the carbohydrates are not used up in the economy, and hence infiltration into connective-tissue corpuscles in the organs of the body takes place and the state known as obesity ensues. The causes of fatty infiltration are, therefore, first, an excess of non-nitrogenous oxidizable matter in the portal blood; second, the deoxidized condition of the portal blood; and, third, the low pressure and slowness of circulation in the portal vessels,—conditions unfavorable to oxidation (Bence Jones) and most favorable to the deposition of particles of fat. Fatty infiltration of the liver is met with as a part of general obesity, as indicated above, and in conditions of diminished oxidation, such as occur in tuberculosis. Rich food, deficient exercise or aeration, and the use of alcohol are the prominent causes of fatty infiltration.

The term "fatty degeneration" is properly applied to the process which takes place in the liver, for instance, when the components of the hepatic cells break up and degenerate into fat-particles; this occurs in acute yellow atrophy of the liver and in phosphorus-poisoning. In fatty degeneration due to high temperature the frequency of fatty infiltration compared with that of fatty degeneration is shown by the statistics of Steiner and Neureutter. They are based on a study of two hundred and seventy-two cases. In two hundred and twenty-two of these cases the liver was fatty (one hundred and one boys, one hundred and twenty-one girls). It was amyloid in fifty cases (thirty-two boys, eighteen girls). Of the two hundred and twenty-two cases of fatty liver, fatty infiltration was seen one hundred and eighty-eight times (ninety boys and ninety-eight girls) and fatty degeneration thirty-four times (eleven boys and twenty-three girls).

The conclusions that Steiner and Neureutter arrive at regarding the age and sex of this series of cases, all of which were in children under fifteen years, are similar to the conclusions of other writers. The youngest of the two hundred and twenty-two cases was eleven weeks old, the oldest fifteen years. From the age of one to four it was the most frequent,—one hundred and thirty-one cases; under one year fatty liver appeared in eleven children. The statement of Rilliet and Barthez, that the youngest children were disposed to this far more frequently than the older, was confirmed. This relation is more decided if tuberculous children are separated from the non-tuberculous: one hundred and seven were non-tuberculous; of these a large number (seventy-six) were aged from one to four years. Sex does not have any influence on the development of this condition: one hundred and one boys and one hundred and twenty-one girls were included in the list of cases.

The following table[1] shows the diseases with which fatty liver may be associated:

	TIMES.	BOYS.	GIRLS.
Tuberculosis	70	29	41

In many of the cases put down to other diseases there was also tuberculosis of the bronchial glands, which explains the discrepancy between the first statement as to the number of diseases in which tuberculosis existed (one hundred and fifteen) and the figures given in the table.

The above table confirms the statement of all authors that fatty infiltration of the liver is more frequently secondary to tuberculosis than to any other disease, and Legendre, Steiner, Birch-Hirschfeld, and Rilliet and Barthez refer to different series of cases in proof of this opinion. Enteritis is frequently mentioned, and yet it is more than possible that the fatty infiltration and the intestinal inflammation are associated not as effect and cause, but as coincidence.

Morbid Anatomy.—The liver is enlarged, flattened, and has rounded edges; its surface is smooth, shining, translucent, and feels doughy, so that it pits on pressure. The color is reddish yellow or pale yellow, and a dry and warm knife-blade becomes covered with oil-drops if it is drawn through the liver-structure. Frerichs found in one case 78.07 per cent. of fat in a liver after it had been freed from its water, nearly four times the amount of the remaining portions of the tissue. In a fresh condition the same liver contained 43.84 per cent. of fat, and 43.84 per cent. of water, the remainder of the tissue consisting of cells, vessels, etc. The fat consists of olein, margarin, and traces of cholesterin.

The color of the liver depends very much on the amount of blood in the vessels: if it is abundant the color is much darker. On the other hand, it is difficult to distinguish microscopically a fatty liver from one that is anæmic. The latter is of the same hue, which, however, is not general, but is distributed in yellow spots which are seen on the surface of the liver, due to pressure of neighboring parts, as the ribs.

---

[1] There are evidently typographical errors in the figures of this table.

Microscopical examination of the liver shows the following changes in fatty infiltration: (1) absence of fat in the intercellular spaces; and (2) deposition of fat in the hepatic cells, which are for the most part rounded and lose their sharp contour. The appearances of the liver-structure in fatty degeneration are similar to those presented in acute yellow atrophy of that organ.

Symptoms.—Symptoms of fatty liver are not special. Either the disease which is associated with the degenerated liver presents its own symptoms, or only the symptoms and conditions which arise in children of sedentary life, who take rich food,—such as the symptoms of indigestion and the general state of obesity,—are found.

Betz includes in the symptomatology of fatty liver the following series of phenomena, which he admits may occur in fatty nutmeg-liver, and the last of which, it is seen, may be due to, or actually are the causal factors in the production of, the fatty liver. They are (*a*) emaciation; (*b*) hectic fever; (*c*) a withered, fine velvety, pale yellow, anæmic skin; (*d*) the above with or without one of the following forms of disease: tuberculosis; carious and carcinomatous processes, connected with imperfect oxidation of the blood; chronic intestinal catarrh; rachitis; alcoholism. The latter is rarely found in children.

The urine has been studied by Horaczeck,[1] who believes that a variegated rainbow-colored pellicle is found on the urine in fatty liver. Betz says that in true fatty liver the formation of urea, uric acid, and urine-pigment must be lessened more than in a fatty nutmeg-liver. He thinks that the appearance of a pellicle on the urine may support the diagnosis, but that of itself it has no value.

The recognition of fatty liver depends chiefly upon the physical signs determined by inspection, palpation, and percussion. Not generally is the liver seen to be enlarged, nor are the lower ribs usually prominent, but an abnormal fulness of the epigastrium is common. On palpation the surface of the enlarged liver is smooth and free from pain. The border of the liver is thick and even. The surface presents the same degree of resistance as in health, and hence the borders cannot be so well palpated. On percussion the liver is found to be enlarged uniformly in all directions. The increase in dulness is more marked in the epigastric region. It is important to remember that the splenic dulness is not increased, but even may be diminished, while the absence of jaundice and ascites may be noted. If jaundice should occur, it must be due to an accidental cause, and in children most likely to a gastro-duodenal catarrh.

Horaczeck considers hereditary predisposition most significant for purposes of diagnosis. Of course this implies a knowledge of the tendency to the special tissue-changes of the family to which the patient belongs.

---

[1] Schmidt's Jahrbücher, Bd. xlvi. S. 303.

It is to be remembered that fatty liver may exist without any noteworthy attending disease, and even without any disturbance save that caused by its size, such as pressure upon the right side when lying on the left. The absence of symptoms should not, therefore, exclude the diagnosis of fatty liver.

The origin and occurrence of the fatty liver, as well as the ultimate changes it may undergo, are of interest. Its occurrence in the first years of life has been referred to. There are observations sufficient to show an intra-uterine origin. Senlen describes the case of a dead-born child, nine months old, the father of which suffered with jaundice and dropsy. The liver of this child weighed one pound and nine ounces, and was fatty.[1] Frerichs found fatty liver in new-born children and in children a few weeks old.

Betz well shows that we know practically nothing concerning the beginning of and concerning certain changes in this disease. He thinks variations in volume should be observed in fatty liver, and he warns us how easily we can be deceived in determining its changes. That they do take place there is no doubt. They are not temporary retrogressions or cessations in the fatty metamorphosis. Whether or not the fatty liver of childhood can remain latent or stationary up to adult life and then develop rapidly, we do not know. He thinks a recovery is inconceivable if the degeneration of the liver-cells seen in fatty hypertrophy is present. Apparently in some cases the liver takes on retrograde changes and gradually becomes cirrhotic. The writer recently had under observation a patient who had a very large fatty liver. It diminished under observation. Death took place from acute disease, and the liver was found to be cirrhotic.

Steiner and Neureutter relate the case of an eleven-months-old child, of healthy parentage, which had tuberculosis accompanied with enlargement of the liver. At the autopsy the changes of rachitis, anæmia, and double pneumonia were found, and the tissues were intensely jaundiced. The liver was enlarged. Shallow depressions on its upper surface were seen. On section the structure was stained with bile, and was fatty and doughy. The bile-ducts were pervious, and the gall-bladder contained clear, watery, viscid fluid. From the description one would not think this a case of cirrhosis.

A second case appears to prove more fully their belief that the decomposition of fatty infiltrated cells and resorption of the fat may result in a kind of granulated liver. A little girl, five and a quarter years old, in poor circumstances, was admitted to the hospital, with cough and diarrhœa; she was emaciated, had enlarged glands, tuberculosis of the lungs, and enlarged liver. Dropsy and sweats developed, and death followed. Tuberculosis was found at the autopsy. The liver was much enlarged, its border rounded, the upper and lower surfaces deepened in places and scarred. The color of its surface was clear yellow, spotted with bile, and red in places. On section the surface was of an intense grayish yellow, firm, the acini were recognized only in discrete red spots of indented form, and the capsule was the seat of inflammation.

---

Diagnosis.—The diagnosis of fatty liver is usually made by exclusion. If in the course of tuberculosis or the associate diseases already mentioned one finds an enlarged liver, with all the characteristics indicated in the symptomatology, and without hepatic symptoms or enlargement of the spleen, the affection is in all probability fatty infiltration of the liver. The absence of albuminuria and polyuria, the absence of enlargement of the spleen, and the differences in the physical characters of the respective forms of liver-enlargement, exclude amyloid disease of that organ. Much importance has been attached by writers to the concurrence in fatty liver of similar degeneration in the heart and the kidneys when this affection is found in adult life. The conditions which favor these changes in the heart and kidneys of adult life do not obtain in early childhood, and hence we do not expect to find them. Indeed, frequently they are simply the changes which come with the normal changes of the aging process.

Fatty degeneration of the liver, as indicated in speaking of the etiology, is secondary to grave general or local processes, does not cause enlargement of the liver, and hence does not call for discussion in this section.

Prognosis.—The prognosis depends upon the associated phenomena, as tuberculosis or other general disease. In the fatty liver which results from errors in diet or from lack of exercise, if the conditions are controllable, the prognosis is favorable.

Treatment.—The treatment of fatty liver implies a treatment of its cause, the methods of which are obvious from a knowledge of the etiology, —namely, alteration of the habits of the child, and, if necessary, change to a climate which will admit of constant exercise in the open air. Farinaceous, fatty, and saccharine articles of diet are to be excluded, as well as alcoholic liquors. It is said that cod-liver oil must not be used when fatty liver is present, even if the drug is indicated for the primary disease. The medicinal treatment must be directed mainly to correction of the digestion and regulation of the bowels. The use of alkalies and alkaline waters has been recommended, and, if practicable, a course at Carlsbad or Vichy, or at springs of like nature in this country, may be advised.

AMYLOID LIVER.

Amyloid, albuminoid, or lardaceous degeneration of the liver is one of the most frequent forms of painless enlargement that occur in childhood. It is not a disease that is confined to the liver alone, the spleen, the kidneys, and the intestines being likewise affected.

Etiology.—This degeneration, like fatty degeneration, is also secondary to tuberculosis, as well as to chronic bone- or joint-disease (usually tubercular), syphilis, and most frequently to prolonged suppuration or any purulent discharge. Empyema is one of the most frequent of the last of the four general causes indicated which give origin to this affection.

Steiner and Neureutter have detailed forty-seven cases of amyloid disease of the liver, divided as to cause as follows:

Frerichs found, in fifty-three cases, three under ten years, and nineteen between ten and twenty years of age; and in Wagner's forty-eight cases, five were under ten and five between ten and twenty. Descroizilles says that it is met with especially between the ages of ten and twelve, and in boys oftener than in girls. Birch-Hirschfeld considers it to be most frequent in children from four to fifteen years of age. All agree that the affection is of frequent occurrence, and yet the literature of the disease does not contain the reports of many cases.

Morbid Anatomy.—The amyloid liver is the seat of general enlargement. Its structure is heavy and dense, the capsule is clear, and on section the cut surface is dry and homogeneous, of a gray color and a glistening appearance. The edge of the liver is rounded. It is almost bloodless on section. The seat of the disease is usually seen to be in the periphery of the acini, the edge of which is light or white. The change usually begins in the walls of the capillaries and arterioles of the hepatic artery, rarely, it is said, in the capsule of the portal vein; thence the deposit spreads to the intra-acinous connective tissue round the affected vessels, ultimately reaching the tissue between the lobules and leading to confusion of their outlines. The connective tissue swells into homogeneous columns, which split readily into flakes like hepatic cells, and which on section look like a mass of degenerate cells or often like whole lobules; careful examination will, however, reveal between the lardaceous masses the liver-cells more or less atrophied and pigmented, the external cells of the zone especially being infiltrated with fat.

The division of the lobule into zones, and the fact that the external zone is the seat of amyloid degeneration, are well known. The internal zone of fatty degeneration and the middle zone of congestion serve to distinguish these forms of hepatic disease anatomically. The iodine test, which causes the parts affected to become a reddish brown when it is applied to a small portion, and the sulphuric-acid test, which changes the affected tissue to a violet and afterwards to a blue color, distinguish this affection.

Of the nature of amyloid degeneration we are not quite certain. It seems that there is primarily an alteration in the blood; probably there is a diminution of the normal mass of albumen. Some think, however, that the tissues are reduced in vitality by the altered condition of the blood, and that the albumen received enters into combination with the protoplasm in such a way as to produce the peculiar substance. Coates, to whom we are indebted for this statement, says the process may be compared to the coagulation of the tissues which sometimes occurs when they undergo necrosis. The tissues apparently enter into chemical union with the fibrinogen in the fluid exuded from the blood-vessels, so as to form fibrin or some substance allied to it. It is essentially a degeneration, but with the addition of tissue from without. Green says that in children especially—though very rarely, it is true—the degeneration may seem to be primary.

Amyloid substance, or lardacein, is an amorphous, white, friable substance that appears to be a fibrin derivative. It occurs only as a pathological product, and in the liver as an infiltration. It is insoluble in water, alcohol, ether, dilute acids, and the alkaline carbonates.[1]

It may not be out of place to indicate the course of amyloid disease in childhood by reference to one of the best reported cases on record, before discussing the symptoms. Pilz details the history of a girl thirteen years old who is said to have been well until her fifth year, when a suppuration of the dorsum of the left hand developed. It continued, and in the course of time a fistula of the rectum appeared. From the eighth year a hardness was noticed in the right hypochondrium. Œdema of the ankle and foot had occurred at intervals two years before. During this time the special symptoms were repugnance to meat food and frequent attacks of diarrhœa, the stools having the odor of carrion.

When admitted to the hospital, the patient assumed a dorsal position; she had a pale, waxy-hued skin, and a marked net-work of veins on the abdomen; the extremities were œdematous, the skin dry, the belly much swollen, with marked undulation; the circumference at the navel measured seventy-eight centimetres, and between the xiphoid and the navel seventy-nine centimetres; while the distance between the xiphoid and the navel was twenty-nine centimetres. The liver in the middle line measured fourteen centimetres, and reached beyond this line to the left eighteen centimetres. In the mammary line it measured nineteen and a half centimetres, and in the axillary line twenty-three and a half centimetres. There was decided ascites. The urine amounted to six hundred cubic centimetres, had a specific gravity of 1016, was acid, and contained much albumen.

---

[1] Charles, Physiological and Pathological Chemistry, p. 120.

During the time she was under observation, there were bloody vomiting, bloody stools, increase in dropsy, and profuse discharge of pus from the fistula, which resulted in exhaustion and death six weeks after admission. Pilz states that while under observation the pulse was steadily accelerated: on May 23 it was 90, on August 1, 80 to 86, on August 2, A.M., 68; and at other times it was above 100,—on the average between 110 and 120 beats to the minute. It was also small. The respirations were accelerated and shallow, between 36 and 46, rarely 56. The temperature in the axilla varied between 98.6° F. and 100.4° F., and therefore was never lowered, as Taylor has suggested is the case in amyloid disease of the kidneys.

The body-weight of the child on July 13 was fifty-three pounds and five ounces, and on July 27 fifty-seven pounds and seven and a half ounces. This increase in weight was due mainly to the increased transudation.

Autopsy.—Liver adherent in great extent to the diaphragm, weight six pounds and eleven ounces, appearance that usual in amyloid disease of the liver. Pilz remarks upon the relative weight of the liver and that of the body,—six pounds and eleven ounces to fifty-seven pounds and seven and a half ounces, or as one to eight and a half. He says that in cases known to him this weight has been surpassed in absolute weight only by one of Steiner and Neureutter's cases, in which, in a thirteen-year-old boy with suppuration of the right psoas muscle, the liver weighed seven pounds and ten and a half ounces, and in proportional weight only by a case observed by Murchison, in which a boy with suppuration of bones had a liver weighing sixty-nine ounces, which was one-seventh of the body-weight. The disproportion in weight is still more striking when the normal relation is given, which, according to Frerichs, is for the eleventh year 1 to 25.56, while with a body-weight of twenty-five thousand and eighty grammes the liver weighs nine hundred and seventy grammes. Pilz compares the size of some enlarged livers with that in the amyloid cases just given, and shows the great preponderance of the latter. It is worthy of note that there was also some fatty change, especially in the periphery of the lobules, besides a great development of connective tissue between the lobules,—associated pathological changes which are frequently found with this affection.

Symptoms.—The rather full abstract of the case just quoted was given in order to indicate the usual course and symptoms of this disease. In general it may be said that the symptoms are of three kinds,—(1) the general symptoms or cachexia due to the amyloid change; (2) symptoms of amyloid disease in other organs; (3) symptoms due to enlargement of the liver,—in other words, mechanical.

Of course the symptoms depend upon the primary disease very largely, and this is notably true with regard to the cachexia. If the causal disease has a cachexia of its own, the amyloid cachexia is not so pronounced, although the general symptoms—that is, emaciation, prostration, and general pallor or anæmia—are more grave and more rapid when amyloid degeneration begins. If the underlying disease has no cachexia, we see with the commencement and development of amyloid disease increased pallor. The skin becomes of a pale white or waxy hue. Anæmia is marked, and local and general œdema, followed by general anasarca, soon arises.

The most important symptoms of local origin are due to enlargement of the liver. On inspection, the marked bowing of the lower part of the right thorax and great fulness in the upper abdomen can be readily seen. By palpation, if emaciation exists or if great meteorism or ascites does not interfere, the lower border of the liver can be felt. The edges are rounded and firm. The surface of the organ is smooth, and the normal fissures are deepened. Pressure does not cause pain, unless a perihepatitis exists simultaneously, as may occur in syphilis. On account of the enlargement, the respiration is usually quickened, but is regular. The heart's action is increased in frequency, while as the disease progresses it becomes enfeebled. The veins over the abdomen are sometimes dilated, though rarely, and never to the same extent as in cirrhosis.

Associated with this disease in the liver, similar disease almost always develops in the spleen and the kidneys, and probably in the gastro-intestinal tract. The spleen becomes enlarged, and thereby increases the size of the abdomen, and hence interferes with respiration and circulation. With the involvement of the kidneys albuminuria is found, polyuria is marked, and the urine is of the low specific gravity of this disease. Casts are found on microscopical examination. With the development of the disease in the kidneys, dropsies, which may occur without it, are likely to be found. Ascites, notably absent in uncomplicated amyloid disease of the liver, is present, while œdema of the face, the feet, and the hands also arises. The failing circulation favors the occurrence of these dropsies.

The gastro-intestinal symptoms are usually marked. It is particularly noted by some that the patient has a special aversion to meat but otherwise has a very good appetite. In other cases a desire for food is much diminished, nausea is marked, and vomiting is a common symptom. The intestinal functions are also disturbed: more or less meteorism occurs, while diarrhœa is most usual. The stools are brownish yellow and foul-smelling. The carrion-like odor of the stools has been frequently remarked by writers.

Frerichs found in twenty-three cases of amyloid liver simultaneous enlargement of the spleen fourteen times, in some instances with amyloid degeneration of that organ. The diarrhœa in the later stages becomes most obstinate, and is dysenteric in character. While so prominent a symptom, and apparently indicative of extreme organic change in the intestines, yet a post-mortem examination always reveals no evidence of inflammation of the bowel.

The duration of amyloid disease of the liver cannot be determined, because the first stages escape observation. Birch-Hirschfeld states that it is not always uniformly progressive, and that the hydræmic symptoms often disappear for a long time and the local symptoms may become milder. The anæmia is not wont to lessen. Death may be due to the primary disease, to local or general dropsies, to exhaustion following uncontrollable diarrhœa, or to the complications, as peritonitis and pleurisy.

The *prognosis* is very unfavorable when the symptoms are so distinct that a diagnosis can be made.

The *diagnosis* of amyloid disease of the liver is not usually difficult when the disease is fully developed. The cachexia, the enlarged smooth hard liver of uniform size and without pain, associated with enlargement of the spleen, albuminuria and polyuria developing in the course of tuberculosis, syphilis, or chronic suppuration, make up a picture not difficult to recognize.

Treatment.—1st. Treatment of the primary disease if possible.

2d. The use of a nutritious diet easily digested, associated with a moderate amount of stimulants.

3d. Residence in a mild and equable climate.

4th. The use of medicines which may possibly influence the chemical changes which take place in amyloid disease. Of these the most prominent are the alkalies. Dr. Dickinson urges their use. He thinks the salts of potassium which are administered compensate for the discharge and prevent amyloid disease. He prescribes a mixture containing the liquor potassæ with the phosphate and citrate of potassium and tartrate of iron.

Tonics, of course, are to be used, and, on account of the profound anæmia, one would expect service from the various preparations of iron. Murchison has seen marked improvement under the continued use of nitric acid in combination with a vegetable bitter. He recommends the external use of nitro-muriatic acid over the liver. Frerichs states that during the long-continued use of cod-liver oil amyloid disease has developed. Its value, therefore, is questionable. Iodine has many advocates, and it or its preparations would undoubtedly be of service when there is a clear syphilitic history. For similar reasons mild doses of the bichloride of mercury may be used. Wetzlar recommends the mineral waters and baths of Aix-la-Chapelle. Begbie advises the use of the chloride of ammonium in large doses. He has observed a great reduction of the size of the liver, and Budd has observed cases where marked improvement occurred when the carbonate or chloride of ammonium was used.

The therapeutic skill of the physician is more strongly taxed in the treatment of the complications of this affection than in the treatment of the disease in general. In spite of the best therapeutic measures, the symptoms often are uncontrollable. The diarrhœa, for instance, while astringents both mineral and vegetable may be used, with or without opium, and the diet regulated, will sometimes resist all treatment and cause the patient's death. Persistent vomiting likewise is most difficult to control.

Careful feeding, the use of preparations of pepsin, of alkalies, of bismuth, and of hydrocyanic acid, and external counter-irritation, are to be tried.

The dropsy, too, is very difficult to treat. The diuretic preparations and combinations of the salts of iron are of the most service, though they are difficult to use if the stomach is irritable; when this is the case, the salts of potassium that act on the kidneys may be given, preferably in effervescence. Purgatives must be given with caution, on account of the natural tendency to diarrhœa. Drugs which stimulate the circulation are to be used. Digitalis, if borne, is a most valuable diuretic and tonic. Cocaine in small doses meets two indications: it is often excellent to relieve vomiting, and at the same time is a good diuretic. The salts of caffeine may be used for a similar purpose. As remarked above, the association of such pronounced complications causes a group of symptoms which it is almost impossible to overcome.

HYDATID DISEASE OF THE LIVER.[1]

Hydatid disease of the liver is produced by the development within the liver of the *tænia echinococcus* in its larval condition. The life-history of this tape-worm has been very carefully studied, and whoever is interested in the subject will find full descriptions of the parasite in the writings of Leuckart, Cobbold, and Davaine: it will be sufficient for our purposes, however, to state that the adult tape-worm is found in the small intestine especially of the dog, and that the minute eggs, passing out with the dog's fæces, are swallowed with the food and drink by human beings, as well as by a number of other animals. When the eggs are thus swallowed, their shells are dissolved, the embryos thus become liberated, penetrate the mucous membrane of the bowel, and may travel to any part of the body; but from the greater frequency of hydatid disease in the liver it has been inferred that the embryos preferably enter the portal vein or its branches, and so are carried in the blood-current to the liver. Wherever the embryo becomes fixed in position it becomes the point of origin of a hydatid tumor.

Frequency.—It is self-evident that the longer a person is exposed to the danger of swallowing eggs of the *tænia echinococcus*, the greater will be the probability of his contracting hydatid disease. For this reason the frequency of the disease increases, as Thomas has admirably demonstrated, with every decade up to fifty, when it falls, because there are fewer alive to become infected. But while children, for the reason just given, are much less likely to have the disease than adults, they are by no means exempt from it.

---

[1] For this division of the general subject of enlargements of the liver, the author acknowledges his indebtedness to his friend and former student, Dr. Herman B. Allyn.

Hydatid disease is found in almost every country about which we have accurate medical knowledge. It is not influenced by climate, for it is especially prevalent in Iceland and in Australia, and it is not uncommon throughout the northern portions of Europe. Intimate association with dogs, coupled with lack of care to see that the water and food are not contaminated with the eggs of the parasite, no doubt accounts for the prevalence of the disease in Iceland and Australia. It has been estimated that in the former country one-seventh of the population has the disease. Dr. John Davies Thomas has shown that the disease plays a very important part in the mortality of Australia, and he gives some surprising and interesting information concerning the wide area of distribution of hydatid disease throughout the world.

Hydatid disease is almost unknown among native-born Americans. Dr. Osler has been able to collect records of only sixty-one cases in America, a third of which probably occurred in foreign-born persons, leaving only forty native cases. Only one of the sixty-one cases was in a child. It would appear that our immunity from the disease is to be explained by more careful habits of living, since Osler has demonstrated that the adult echinococcus is found in dogs and other animals in this country more frequently than is commonly supposed, and it is a matter of common knowledge that there are large cattle- and sheep-ranches in the western and southwestern sections of the United States.

There is reason to believe, also, that it is not so rare in children as many writers have asserted. Birch-Hirschfeld found twenty-seven cases of hydatid disease of the liver in a review of the literature, which he states was by no means complete; and he says that Finsen has found forty-one cases in Iceland in persons under fifteen years of age, and Thorstensen has recorded twenty-six cases in children under ten. Thomas, in his table of five hundred deaths from hydatid disease occurring in Victoria between the years 1868 and 1881, records thirty-six cases in children under ten years of age, and fifty-seven between the ages of ten and twenty; in New South Wales the number of deaths in persons under twenty years of age, between 1875 and 1881, was thirteen; in Queensland there were two deaths between 1878 and 1881, and in South Australia there were seven between 1866 and 1882. This gives a grand total of one hundred and fifteen fatal cases in persons under twenty years of age. Of course in the majority of these cases the liver was the seat of the disease. No record is given of cases in which recovery occurred. The writer has been able to collect, from French, German, and English sources, records of thirty-three cases of hydatid disease of the liver in children of fifteen years or under, exclusive of Thomas's cases. It is evident, therefore, that the disease is not one of extreme rarity in children.

Moreover, the slowness with which the disease develops makes it probable that many of the cases first recognized in adults began in the period of childhood. Budd mentions a remarkable case in which a woman who died at seventy-three was found to have two hydatid tumors, which there was reason to believe had existed since she was eight years old. Barrier[1] mentions a case in which the duration was from fifteen to thirty years, and a number of cases are on record in which the duration has been from two to six years.

Anatomical Characters.—When the hydatid embryo becomes fixed in position, it loses its hooks, grows larger, and from a solid body becomes gradually transformed into a vesicle,—the hydatid cyst. The capsule of this cyst is a connective-tissue membrane formed from the human tissues, apparently as the result of the irritation induced by the presence of the parasite. It is, therefore, no part of the cyst proper. The thickness of the capsule is variable, and probably increases the longer the parasite remains in the body of its host. It is richly supplied with blood-vessels, which nourish both it and the contained parasite; fatal hemorrhage has resulted from rupture of the vessels upon the internal surface. The capsular walls are subject to the same degenerative changes that affect other tissues, but especially to calcareous degeneration.

Within this capsule is found the parasite, transformed into a cyst. The outer wall of the cyst is translucent, lamellar, and very elastic; the inner wall is composed of granular matter, cells, muscle-fibres, and vessels. The fluid contained in the cyst is translucent, and faintly opalescent in transmitted light. It is almost entirely free from albumen, but contains salt in large quantity, abundance of leucin and tyrosin, some grape-sugar, and succinic acid. The latter, Leuckart states, is found in hardly any other living organism. The fluid also contains crystals of cholesterin, and sometimes hæmatoidin,—the latter when hemorrhage into the sac has occurred. The specific gravity of the fluid is placed as low as 1000 by Frerichs, but it probably varies between 1009 and 1015.

Three varieties of hydatid cyst have been described,—first, *Echinococcus granulosus;* second, *E. hydatidosus;* and, third, *E. multilocularis.* In the first variety there is a simple cyst the internal layer of which contains brood-capsules, developed by a budding process from it. These brood-capsules contain the heads, or scolices, of the parasite. The capsules may rupture and allow the heads to float free in the cystic fluid; but in the normal fresh condition they are attached to the cyst-wall. This variety is most frequent in domestic animals, though it also occurs in men.

The second variety, *Echinococcus hydatidosus,* is characterized by the formation of daughter-cysts in the interior of the mother-cyst. The daughter-cysts may be developed in large numbers, even to the number of thousands, and may in turn give rise to grand-daughter-cysts. The continued proliferation of these cysts accounts for the large size of the tumor.

---

[1] Quoted by Birch-Hirschfeld.

Naunyn and Leuckart assert that the daughter-cysts are produced by a retrograde metamorphosis of the heads and brood-capsules. In the case of echinococci which are destitute of heads, it is supposed that the daughter-cysts are produced by a sacculation of the echinococcus wall.

The third variety of echinococcus, *E. multilocularis*, is believed to result from an abnormality of development. It is made up of a large number of very small cysts, closely set, and containing transparent, jelly-like material. The alveolar arrangement visible on section, and the gelatinous character of the contents, led to the belief at one time that they were tumors which had undergone colloid change. To the touch this variety of cyst is firm and resistant; it grows to the size of the fist or to that of a child's head, is comparatively rare, is found almost exclusively in man, and in him almost invariably in the liver.

The three varieties described are simply forms of the same species. The *E. hydatidosus* attains the largest size, is the one most frequently met with, and is consequently the most important from a clinical point of view. Of course more than one form may be met with in the same person.

Symptoms.—The symptoms of hydatid disease of the liver up to a certain point are neither many nor characteristic. The growth of the tumor is slow and imperceptible. Sometimes it is detected only by accident, or when the patient is under examination for some other ailment. The latter was the case in the instance related by Thieberge. A boy six years old, suffering with croup, was found to have two hydatid cysts of the liver. The existence of one of these had been noted by the parents, but neither appears to have given rise to any symptoms. The boy died from extension of false membrane into the bronchi, and the clinical diagnosis was established by the post-mortem examination.

In other cases the existence of a hydatid tumor has been unsuspected until the child has sustained some injury, as in the case reported by Edge. A boy four and a half years old was forcibly grasped around the waist and lifted from the ground by a playmate. He ran home complaining of pain, and his mother found a swelling in the abdomen. Two days later a hydatid tumor the size of an orange was discovered.

The local symptoms of hydatid tumor of the liver depend upon the seat of the tumor and upon its size. A small tumor situated so as to compress the bile-ducts or the blood-vessels will give rise to jaundice and to vascular symptoms. In a case cited by Pontou, from the service of Triboulet, a girl twelve years old had an enormous liver, filling the right hypochondrium and extending to the iliac fossa and all the sub-umbilical region. The tumor had the physical characteristics of an hypertrophied liver. To increase the difficulty in diagnosis, pressure over the liver was painful, jaundice was present in a marked degree, and there were repeated copious hemorrhages from the nose, and, later, dropsy. At the autopsy there was found an enormous cyst situated behind the liver, and replacing the whole right lobe, except a wall of hepatic substance. In front of this tumor, in the fissure of the vena cava, was another cyst. It was the latter which caused the jaundice and dropsy. But neither jaundice nor ascites is a common symptom.

The most common seat of hydatid disease of the liver is in the right lobe, near its anterior surface. Pontou says that in the cases accurately reported the parasite occupied the right lobe seven times and the left lobe three times, while in four cases it was on the anterior surface and twice on the posterior. It will be readily understood that a tumor of moderate size situated upon the anterior or convex surface of the liver would be detected, whereas if situated on the posterior surface of the liver, or between the liver and the diaphragm, or between the liver and the stomach, it might not even be suspected, especially as subjective symptoms are frequently absent. In Unterhart's case, in a girl nine years old, the cyst developed on the posterior surface of the liver at its upper edge, and pushed the diaphragm up and the liver down. In the first attempt at puncture the trocar struck the liver, but subsequently the cyst was pierced at a point in the nipple line, where there was no prominence.

Sometimes the cyst projects from the inferior edge of the liver as low as the umbilicus, or into the right iliac fossa. At times it develops in the body of the liver, and the dimensions of the latter become enormously increased, the belly is conspicuously swollen, and the edge of the ribs is expanded like the rim of a bell. The subjective symptoms in such a case may be a sense of tension and discomfort in the liver region, with perhaps pain and tenderness if the capsule of the liver is much stretched or if peri-hepatitis coexists. There may also be digestive disturbances, such as constipation, vomiting, lessened appetite, and some loss of flesh. On the other hand, there may be no symptoms except the local ones, and the general health may remain good.

Such a case as the latter statement suggests is recorded by Petel. A boy three and a half years old was brought to Archambault's clinic for an enlargement of the abdomen which had been noticed for a year and had developed gradually. The child had had neither diarrhœa, vomiting, nor jaundice; it had never complained of its belly, and its general health remained good. The belly below the false ribs projected, and palpation disclosed the presence of a tumor situated in the liver. The tumor was round, smooth, and painless, and in volume about the size of a fœtal head. It appeared to be embedded in the right lobe of the liver, and was hard and resisting, presenting neither fluctuation nor vibration. At its most prominent part, however, it exhibited a sort of elasticity which gave the impression that the tumor contained liquid. The child presented no digestive troubles, no œdema of the limbs, and no ascites. The tumor was aspirated and hydatid fluid withdrawn.

It will be seen that in such a case the symptoms, while entirely local, are still sufficient to make a diagnosis.

When the tumor is developed near the surface of the liver and is of considerable size, or when it projects below the liver in such a way that it can be examined through the abdominal walls, it is usually possible to obtain fluctuation, and in a number of cases the so-called "hydatid fremitus" can be developed. This fremitus is nothing but the vibration transmitted to the examiner's hand by sharply tapping a tense thin-walled cyst filled with fluid. To develop this sign, Murchison advises that the three fingers of the left hand be laid flat upon the tumor, and the back of the left middle finger then struck abruptly with the point of the middle finger of the right hand. It was at one time taught, especially by the French writers, that this fremitus was caused by daughter-cysts striking and rebounding from the wall of the mother-cyst; but it may be felt in simple cysts and is entirely independent of the existence of daughter-cysts. Küster relates a case, in a girl nine years old, in which hydatid vibration was very decided. During a radical operation for the removal of the cyst, it was found that only two mother-cysts, bordering on each other, existed, and no daughter-cysts. Küster regards the discovery that two or more adjacent mother-cysts may give rise to hydatid vibration as noteworthy for operative reasons; as, in cases in which the sign has existed and upon operation no daughter-cysts are found, contiguous mother-cysts should be sought for and evacuated.

Up to a certain time, therefore, a hydatid cyst, of moderate and even of large size, may persist without any subjective symptoms and with few if any local physical signs. Sooner or later, however, symptoms appear, from the pressure exerted by the enlarging tumor, and from the resulting interference with the function of the liver and with surrounding viscera. Birch-Hirschfeld states that after the favorable general condition—which is all the more striking in contrast with the demonstrable tumor—has lasted for a long time (generally a year), emaciation usually begins, the skin simultaneously becomes increasingly pale, and digestive disturbances appear. Sometimes at this stage hydræmic symptoms begin. Gerhardt maintains that emaciation is wont to occur more quickly in children than in adults.

While pain over the liver and fever are usually absent, they occur in some instances as the case progresses. In the case related by Stromszky, a boy eight and a half years old applied for treatment on account of frequent stabbing pains in the right hypochondrium, in which region a swelling had been noted for six months. The liver was enlarged and projected two finger-breadths below the edge of the ribs. During the succeeding few months the symptoms consisted of gastric disturbance, obstinate constipation, pains in the abdomen, and fever. As the liver slowly enlarged, the symptoms became more marked, and there were added to those already mentioned headache, loss of appetite, troublesome swelling of the abdomen, and so bad a general aspect that typhoid fever was suspected. The subsequent symptoms in this interesting case may be briefly mentioned, for they illustrate the effects of the gradually-increasing pressure of a tumor of the liver upon the circulation, respiration, and general nutrition of the child. The child lost flesh, and became increasingly pale; with the progressive enlargement of the liver, the belly steadily increased in size until it measured eighty-four centimetres in circumference and the distance from the xiphoid cartilage to the symphysis pubis was thirty-nine centimetres. Thick bluish veins appeared about the navel and extended upward to the middle of the thorax and beyond on the right side. Œdema occurred, and some dyspnœa; subsequently the œdema increased, ascites developed, gangrene of the scrotum set in, and respiration became increasingly embarrassed. Fever was continuous during the later stages, and death resulted from exhaustion about fifteen months after the swelling over the liver was first noticed. An autopsy confirmed the diagnosis—arrived at late—of hydatid disease of the liver.

But, apart from the pressure-symptoms arising from the gradual development of a hydatid tumor, which are so well portrayed in the case just cited, special symptoms occur from rupture and from inflammation and suppuration of the sac. Rupture took place in one-third of the four hundred and fifty-one cases of hydatid disease of the liver collected by Neisser. It occurred as follows: into the alimentary canal in forty-five cases, into the bronchi after perforation of the diaphragm in thirty-one cases, into the peritoneal cavity, into the pleura, and externally, in sixteen cases each. Rupture occasionally occurs also into the veins, ureters, and bile-ducts.

The symptoms following rupture of a hydatid cyst into the peritoneal or pleural cavity are those of acute suppurative peritonitis and empyema, and need not be dwelt upon in detail. Death is the usual result. When rupture into the intestine occurs, the fluid and daughter-cysts may be discharged by the bowel; though if the fistulous communication with the intestine is high up, they may be vomited. As a rule, however, the cysts are ruptured before being discharged, and only shreds of membrane, which require the microscope for their proper recognition, appear in the stools. If rupture occurs into the veins, the symptoms are those of phlebitis, or thrombosis, or local gangrene. When rupture occurs externally, a fistulous communication with the sac is established, through which the contents of the cyst are gradually drained. Of course, as the result of this fistula, suppuration of the sac may occur, and peritonitis develop later. When rupture occurs into the bronchi, the fluid and cysts or shreds of membrane are expectorated, and recovery is the rule.

Suppuration of the cyst occurs in some cases, and may be discovered before tapping or not until afterwards. In a case reported in the thesis of Pontou, from the service of Giraldes, suppuration of the sac was discovered when the cyst was incised, and after death there were found metastatic abscesses of the liver. While the pus is confined to the sac, there may be no symptoms in addition to those already mentioned, since the cyst is practically outside the body so far as connection with the circulation is concerned. But if adjacent structures are inflamed, or pus leaks from the cyst, there may be pyæmic symptoms.

To sum up: after a variable period during which there are few subjective symptoms or absolutely none, the child is noticed to be ailing, to have a swelling in the right hypochondrium, or a "big belly," and to be affected with digestive disturbances, accompanied perhaps by loss of flesh. Occasional symptoms at this stage are pain, fever, jaundice, and œdema. The liver is generally enlarged. Subsequent symptoms are produced by the pressure upon adjacent organs of the enlarging tumor, by the rupture of the tumor, or by inflammation and suppuration of the sac.

Diagnosis.—The diagnosis of hydatid tumor of the liver is in some respects easier in children than in adults, with the important exception that its relative rarity may lead the medical attendant to overlook the possibility of its occurrence. Diagnosis is easier in children because distended gall-bladder, phantom tumor, and aneurism, with which diseases hydatid disease of the liver in adults is liable to be confounded, are so rare in children that they may be left out of the count in diagnosis.

Hydatid tumor of the liver may be mistaken for an enlargement of the liver due to hypertrophy, to fatty and amyloid degenerations, or to malignant disease,—sarcoma or carcinoma.

When the hydatid tumor develops within the body of the liver, or behind it, in such a way that as the liver becomes steadily larger a shell of hepatic tissue is left between the cyst and the chest-wall and abdomen (as in Stromszky's case), it may be impossible to make a correct diagnosis; especially if, as in his case, puncture fails to strike fluid. But hypertrophy of the liver to such an extent as to produce serious pressure-symptoms must occur extraordinarily rarely.

In fatty liver the antecedent history is different from that obtained in hydatid disease, the constitutional symptoms are much more marked, and ordinarily the local conditions are very different. In fatty liver there is a general, uniform, smooth enlargement of the liver in a tubercular child, or in one overfed on fat-producing foods; while in hydatid tumor we have a round, smooth, painless tumor, usually unaccompanied with fever, much disturbance of the general health, or local tenderness. If in addition fluctuation of the tumor and hydatid fremitus can be detected, there would seem to be little probability of a mistake in diagnosis. Whether fluctuation and hydatid fremitus are present or not, a tumor suspected to be a hydatid cyst should be punctured. If an apparently colorless and non-albuminous fluid, containing abundance of chloride of sodium, is obtained, the probability that one has to do with a hydatid cyst is much strengthened. The diagnosis may be considered settled if hooklets are found in the fluid. In very obscure cases it would be well to examine a suspected fluid for sugar, leucin and tyrosin, crystals of cholesterin, and succinic acid.

If the patient with enlargement of the liver is pale, anæmic, sickly, and somewhat emaciated, the possibility of amyloid degeneration must be remembered. But in the latter disease both the local and the constitutional symptoms are usually very different, as there can generally be obtained a history of syphilis or prolonged suppuration: an examination of the spleen for enlargement, and of the urine for the characteristic evidences of amyloid disease of the kidneys, will shed light upon any obscurity. Furthermore, if hydatid disease of the liver has lasted long enough to produce constitutional symptoms simulating those of amyloid disease, it will almost always be possible, by repeated attempts at puncture, to obtain hydatid fluid and thus establish the diagnosis.

With regard to malignant disease of the liver, consisting of sarcoma and carcinoma, it should be borne in mind that in countries in which hydatid disease is most likely to be found the latter will be much more common than the former. Not much difficulty is likely to be encountered in differentiating the two, however; for in malignant disease the duration is much shorter, and it is characterized by pain, tenderness, progressive failure in nutrition, and emaciation, and by greater digestive derangements than occur in hydatid disease. Jaundice, ascites, and fever are also more common in the former than in the latter. Moreover, the enlargement of the liver is usually irregular and nodular. In very soft cancer a deceptive sense of fluctuation might lead to error, but the result of puncture with a hypodermic needle will be sufficient to prevent any mistake in diagnosis.

Abscess of the liver is distinguished from hydatid disease by the more acute character of its symptoms and by their more rapid development. While in most cases abscess is probably secondary, nevertheless the onset of the hepatitis is marked by chill, fever, pain, tenderness, and a profound disturbance of the general health. Tumor occurs in both; but the tumor in abscess is seldom well defined, is rarely as large as a hydatid tumor, and presents physical characteristics very different from those of the typical globular, painless, fluctuating and vibrating cyst. It should not be forgotten, however, that suppuration may occur in the cyst, or in the liver surrounding it. The diagnosis may then be extremely difficult, but practically is not of great importance. In a case reported by Pontou, which has been referred to already, it will be remembered that metastatic abscesses of the liver occurred secondarily to suppuration in the cyst.

Cystic enlargements of the kidney can usually be distinguished from a hydatid cyst of the liver by their location, by the direction of their growth, and by the fact that they do not move with the liver upon deep inspiration. It may be possible, also, by careful palpation, to discover that they are unconnected with the liver, but lie along the vertebral column, from which, according to Birch-Hirschfeld, they cannot be separated. An examination of the urine may assist greatly in the diagnosis.

Effusion into the right pleural cavity presents some points of similarity with hydatid tumor of the liver. But the fluid in the former is free to move, and hence occupies a different level with the changed position of the patient. The history of the two affections is different, and so, of course, is the character of the fluid. Moreover, in the former there is no enlargement of the liver, though it may appear enlarged from the fact that it is pressed down so as to project below the edge of the ribs. In pleural effusion there are generally cough, fever, and greater dyspnœa than is likely to exist in hydatid tumor. In estimating the probabilities it is well to bear in mind that the two affections may coexist, and that, according to Murchison, an encysted pleurisy may simulate a hydatid tumor by producing a circumscribed bulging of the lower ribs.

Duration.—The duration of hydatid tumor of the liver is extremely variable. It may last a few months or nine or ten years. In a single case Barrier established a duration of from fifteen to thirty years. The case mentioned by Budd, in which a woman seventy-three years old was believed to have had a hydatid tumor since her eighth year, has been referred to already. The duration in most cases is probably from two to four years. It appears to depend upon the location of the cyst, upon the vitality of the echinococcus, and upon the power of resistance of the fibrous capsule formed from its host's tissues. Where great resistance is offered to the expansion of the cyst, and where the vitality of the echinococcus is low, growth will be slower. It would appear, also, that when the vitality of the parasite has been lowered by excessive production of daughter-cysts, and especially when calcareous degeneration has affected the fibrous capsule and the animal is thus deprived of nourishment, its death may follow.

On the other hand, an accident or an injury may lead to rapid development of a cyst before apparently latent, or at least enlarging very slowly.

Prognosis.—Judging by the statistics at hand, hydatid disease of the liver is more fatal in children than in adults. The cases tabulated by Thomas, and already mentioned, were all obtained from mortuary records, so that only a very general inference can be drawn from their number. In the thirty-three cases collected by the writer, there were twenty-two recoveries and nine deaths; in two cases the result was not stated. It will be readily understood that a hydatid cyst so situated as to press upon the vessels of the liver will be a source of greater danger than one which is free to grow into the abdominal cavity. In the latter situation, also, the prognosis would be more favorable, because the cyst could be recognized and aspirated more readily. While in some instances the parasite dies, the contents of the cyst become transformed into a putty-like or plaster-like mass, and its walls undergo calcareous degeneration, this spontaneous cure is the exception, and there is no known way of producing it artificially. If the parasite continues to live and the cyst to grow, the result will be the death of its host, unless the contents of the cyst are evacuated, either spontaneously or artificially. The prognosis is, therefore, more favorable when the disease is recognized early and admits of operative treatment.

The gravity of the prognosis is greater when there are a number of cysts than when there is only one, and when secondary tumors form, and is gravest in the multilocular variety. In the latter death almost always results. It is a curious fact that most of the cases hitherto reported (nineteen out of thirty-five, according to Neisser[1]) have occurred in Switzerland, and in Germany it is found almost exclusively in the south.

Rupture externally, into the intestine, and into the bronchi, is, in general, a favorable issue; but when rupture takes place into the peritoneal or the pleural cavity, or into the veins, death is the usual result. It is probable, however, that the increased success which surgeons have achieved in dealing with affections of the abdominal and pleural cavities will in future lessen the mortality from rupture of hydatid cysts into these cavities. Rupture into the bile-ducts is an unfavorable issue.

Other complications, such as suppuration of the sac, with or without subsequent rupture, pleurisy, pneumonia, peritonitis, and the development of severe pressure-symptoms, all add in varying degrees to the gravity of the prognosis.

In the average case, when there is but one cyst, and that is susceptible of operative treatment, the prognosis is good.

Treatment.—Hydatid disease is pre-eminently a preventable disease. So far as man is concerned, it may be stated as an axiom that where there are no dogs there will be no infection with the echinococcus. The custom of having a dog as a household pet, which is allowed to lick the hands and faces of the children, is not free from danger in any country, but it is highly objectionable in those countries in which hydatid disease is prevalent, and is especially so with dogs engaged about sheep, hogs, and cattle. Dogs should be prevented from feeding upon the offal of the animals just named, and the water-supply for drinking purposes should be guarded against contamination. One of the best safeguards against infection is undoubtedly an intelligent appreciation of the danger to be incurred. This of itself will lead to greater cleanliness in habits of living, to a wholesome nicety in the choice of food, and to its proper purification and cooking. The food of the dogs should also be cooked.

Internal remedies, to destroy the parasite or to modify its course, are useless. Iodide of potassium and common salt were thought at one time to have this power; but how little can be expected from any medicine will be best illustrated by recounting the experience of Dr. Leidy. He says that he once received for dissection the body of an English sailor which had been injected with zinc chloride for preservation. In the abdominal wall in the right iliac region there was a hydatid tumor the size of a fist. On examination of the tumor it was found full of daughter-cysts, and these contained living scolices, though the man had been dead several days and the tissues were bleached by the zinc solution.

It will be evident from what has been said under prognosis that effective treatment is surgical. In many cases aspiration is all that is necessary. In others incision appears to be required.

TUMORS OF THE LIVER.

Under the above general term all forms of tumors of the liver will be included. The writer has been able to collect nineteen cases of primary malignant disease of the liver, divided as follows: adenoma, two cases; lymphadenoma, two cases; carcinoma, ten cases; sarcoma, five cases.

The clinical account in these pages will be based on an analysis of the cases above noted. In addition some tumors of the liver have been reported which were not malignant in character, but which were no doubt the primary cause of death. They are rare, and will be found in the abstracts of cases which the writer has added to this section. (Cases XIX., XX., and XXI.)

Of these, the case of Luschka presented some features of interest. At the birth of the child, which was premature, the abdomen and veins were enlarged and the skin was pale yellow. Twelve days after birth, hemorrhages from the cord, the stomach, and the bowels took place, with œdema of the lower limbs. Four weeks after birth the child died. At the autopsy a round fleshy tumor was found which had its origin in a hemorrhage into the parenchyma of the liver. Except the enlarged veins and prominent abdomen, the symptoms were like those of malignant jaundice. The case of Hueter presented symptoms which, in the occurrence of pain, enlargement of the abdomen, and presence of a tumor, resembled those of malignant disease of the liver. It was considered to be malignant disease of the kidney associated with ascites. An operation determined the presence of an enormous cyst of the liver which filled the entire abdomen, and in the sac of which a firm mass of clots or necrotic tissue was found which had been detected on palpation and mistaken for tumor of the kidney. The patient recovered.

In addition to the tumors the origin of which is primarily in the liver, secondary tumors are found which cause the same symptoms and are the cause of similar enlargement of that organ. In cancer of various organs of the body the liver is secondarily involved. The primary seat of the growth is often very obscure, and hence practically the liver-affection alone is held to be the process in progress. In other words, the symptoms of the secondary disease in the liver are frequently the symptoms of the disease, and the case is considered one of hepatic disease. It may be taken for granted, therefore, that the symptoms of secondary cancer of the liver are the same as those of the primary form. It will not be referred to again.

We likewise find tumors of the liver associated with or part of a similar process in other organs or structures of the body. Thus, lymphoma, lymphadenoma, or lympho-sarcoma of the liver (Case XXII.) does not usually exist alone, but in conjunction with the same disease in other organs. The cystogenic tumor which Wagner describes and which Birch-Hirschfeld includes in his article on malignant tumors of the liver belongs to the same class. In this case similar growths were found in the small intestine, the peritoneum, and the kidney, but the enlarged liver was in the foreground, and hence the distinguished author quoted thinks it should be treated of as a case of tumor of the liver. So with the other varieties: the hepatic symptoms are the most prominent, and hence the cases are classified under liver-disease. Cases of this class are not included in the following discussion, and are simply alluded to in this instance as examples of enlargement of the liver. An abstract of a case is also appended to illustrate enlargement of the liver from tuberculosis of that organ.

Carcinoma and Sarcoma of the Liver.—Cancer of the liver is rare. Birch-Hirschfeld has noted twice in four hundred sections of new-born children general diffused cancer in the form of roundish nodes whose circumference for the most part did not surpass the size of a pea, which presented no symptoms during life. The rarity of cancer of the liver simply corresponds to the rarity of carcinoma in general in early life. In 1851 Lebert cited fifteen instances of cancer in early life, and in 1867 Duzan mentioned nearly two hundred. This includes cancer of all the organs and tissues. The latter author affirms that cancer in children is almost always encephaloid. Wilkinson and Rokitansky have noted the existence of scirrhus in very young subjects. Descroizilles, from whom the above is drawn, states that cancer occurs exceptionally in the liver, and quotes Charon and Ledegank and also Germain-Sée in support of the statement. He refers to a case which Bouchut met with, and quotes the case of Lewis, of which we give an abstract. Of Bouchut's case we could not find a record.

Of the seventeen cases collected by the writer, six were sarcoma, ten were carcinoma, and one was adenoma of the liver. They are studied together in the following *résumé.*

Etiology.—No cases are included over fifteen years of age. The youngest case was three weeks old; it was a diffused sarcoma. Under one year six cases, or one-third of the entire number, are reported; in the second and the third year, two cases each; in the twelfth year, three cases; and one each at the age of nine, eleven, thirteen, and fourteen years. The sex was not always given. Of the eleven cases in which the sex was recorded, five were females and six were males. In the larger number of cases there was no hereditary history of disease, and in three instances only was there mention of an injury which might have been referred to as the cause of malignant disease.

Symptoms.—The symptoms developed rapidly, and the disease ran a rapid course. Pain in the region of the liver was first complained of usually, without other symptoms. General enlargement of the abdomen was soon observed, and the veins in the abdominal walls were seen to be prominent. With this the liver was found to be enlarged, its surface and edges irregular, and while under observation it grew rapidly and was the seat of pain; or a defined tumor connected with the liver was detected. Gastro-intestinal symptoms accompanied the local symptoms, and emaciation, progressive in character, with increased prostration, soon took place. Fever was observed in a few cases. Jaundice was very rare, and enlargement of the spleen and ascites were notably absent. Enlargement of the veins is more peculiar to children than to adults, in this affection.

In two of the cases no clinical history was detailed. The following account of the symptoms, their character and frequency, is taken, therefore, from an analysis of the fifteen cases in which they were given.

1. *Pain* in the hepatic region was complained of six times, and in the region of the stomach once. In one instance it was seated in the right hypochondrium and extended to the left shoulder. It usually occurred in the beginning of the disease, but in one of the six cases the pain did not occur until the last week of the patient's illness. Tenderness without pain was noted in one instance. In some cases the pain was due to the growth itself, but in most of them to the complication of localized peritonitis.

2. *Enlargement of the Abdomen.*—Enlargement of the abdomen without cause was spoken of particularly in three instances. It is, however, a common attendant of hepatic carcinoma. In one it was said to be firm and livid, in another its surface was said to be irregular, and in the third its character was not described.

3. *Enlargement of the Veins.*—Enlargement of the veins of the abdomen was noted in six cases.

4. *Tumor*, described either as one mass or as a number of projections over the surface of the liver, was found in eight cases. Thus, in one it was said to extend from the sixth rib to the iliac fossa and from the vertebra to the linea alba on the right side. Over its surface elevations, soft in character, the size of a child's fist, were seen and felt. In another it was said that the tumor extended from the chest to the pelvis and that it was firm and immovable. In a third dulness extended from the xiphoid to the hypogastrium and in the lumbar and iliac regions, on account of a smooth resisting mass which filled up the entire abdominal cavity except a small space in the hypogastric region. Practically, the above-described tumors were really due to enlargement of the liver, not independent of or adjacent to it, and hence were not tumors of that organ. They should be studied in connection with the subsequent remarks on enlargement of the liver. Specifically, a tumor was described in the following localities: first, in the epigastrium, to the right of the median line, between the umbilicus and the base of the chest; second, at the umbilicus, like a fluctuating prominence; third, at

first at the last ribs on the right side, before death in the right hypochondrium and epigastrium as an elastic fluctuating mass. In another case the tumor was the size of a hen's egg and was seated in the epigastrium. In the case of West the position of the tumor was not defined. The tumor was the seat of pain twice, and was painless in three instances. The skin of the surface of the tumor was red in one case in which there was fluctuation. While hard and firm in a few instances, it is important to note that it was elastic and fluctuating in three cases. This fluctuation was so marked as to lead to the diagnosis of hydatid cyst or abscess.

The large size and rapid growth and the softening and fluctuation appear to characterize the malignant tumors of the liver in childhood.

5. *Enlargement of the Liver.*—This in five cases was positively said to exist during life, and in five other instances it, presumably, was determined before death, for in each a tumor of the abdomen was described which the autopsy showed to be due to carcinoma of the liver. (See above, under Tumor.) The enlargement was very great, and much greater in proportion to similar diseases of the liver in adults. Thus, in one instance the liver was found by percussion and palpation to extend from the third rib to four inches below the margin of the ribs, or from the chest to the pelvis, and in another to fill the entire abdominal cavity except a small space in the hypogastric region. The surface of the liver was usually irregular, and the elevations or prominences over it have been defined as soft, or elastic and fluctuating, or as bossy swellings which were umbilicated. The fluctuating projections in several instances yielded, on palpation, signs similar to those yielded by a cyst, and were punctured with a view of securing cystic fluid. In all the instances in which aspiration was performed nothing but blood was withdrawn. In one case the liver, it is said, extended from the clavicle to the pelvis.

The same remark as to the size, growth, and character of the tumor of malignant hepatic disease in childhood applies to the organ itself.

6. *Ascites and Œdema.*—This was usually absent. In two cases its presence was determined before death. Œdema of the legs occurred, no doubt from pressure, in three instances.

7. The *spleen* was not enlarged.

8. *Jaundice* was observed in three cases. In one only was the jaundice very deep. No special secondary symptoms were caused by it, and the course of the disease was not influenced by its presence.

9. *Gastro-Intestinal Symptoms.*—Nausea and vomiting occurred in four cases. Diarrhœa was found in three cases, and constipation was noted in one. A striking fact is the great frequency of cases in which the gastro-intestinal were the first symptoms. The illness was ushered in with vomiting and diarrhœa.

10. *Fever* was most marked in one case (Pye-Smith), but was noted also in three other cases. It was associated with a tumor which was soft and fluctuating and which gave rise to the belief that abscess of the liver was

present. The rapidly-growing cancer often causes so-called hepatic fever. It is rather remarkable that this symptom was not more common. It may not have been looked for.

Finally, the character, mode of onset, and progress of the symptoms did not indicate the form of malignant disease present.

Duration.—Usually the cases were of short duration; the longest was under observation seventeen months. The shortest appeared to be a growth of ten days only (Pepper). The sarcomas grew more rapidly and caused death sooner, on the whole, than the carcinomas,—one month, ten weeks, and three, four, and five months, respectively, being the duration in five cases.

No relation between the size of the growth and the duration of the disease could be made out that was of any importance. It may be said, however, that the larger new growths were produced more rapidly. One of the largest of the encephaloid carcinomas was of forty-five days' duration only.

The duration of the ailment had no influence on the character of the carcinoma, if we accept the data of these cases. The example of scirrhus occurred in a child nine months old. This is not contrary to the rule generally regarding the duration of various malignant growths.

Practically, it may be possible to say that if the new formation in the liver grows rapidly it may be a sarcoma.

Diagnosis.—The diagnosis in individual cases was not difficult: indeed, it appears easier to distinguish carcinoma in children than in adults.

Hydatid disease and abscess of the liver were discussed by several of the authorities quoted in the appendix, in connection with their particular cases. The results of aspiration usually led them to exclude these affections. One can appreciate difficulties, however, in a case where, from carcinoma, hepatic symptoms—pain, enlargement of the liver, a tumor, and slight fever—arise after direct trauma. The suffering does not seem to be so great, however, as in abscess, the fever is not so high, and the sweats are not so marked. The liver is generally larger in cancer, and can be percussed and palpated with less suffering. The abdominal veins are more likely to be enlarged. Emaciation characterizes both, but in carcinoma is coupled with cachexia and is very marked. A full discussion of the distinctions will be found in the article on abscess of the liver. Hydatid disease is painless, almost symptomless, and chronic. The tumor is larger and has characteristics described in that section.

We have purposely omitted a description of the anatomical characters of tumors of the liver. In the appended abstracts of cases will be found good individual descriptions. Moreover, they do not differ much from the same structural changes in adults, the characters of which one can readily learn in the vast number of text-books on pathology. That the malignant growths of childhood are more diffuse and more luxuriant than those of adult life, is well known.

Concerning the prognosis and treatment nothing need be added.

ABSTRACTS OF CASES OF CANCER AND OTHER TUMORS OF THE LIVER.

Case I., Encephaloid Cancer.—Girl thirteen months old. For some time she complained of continual suffering. When first seen, in April, 1834, a painless tumor in the liver-region, at the level of the last ribs on the right side, of considerable volume, was found. The skin was stretched over it and brilliant as in phlegmonous erysipelas, but presented only slight redness and no pain on pressure. Appetite good; no fever; no general trouble. After three months the tumor occupied the right hypochondrium and epigastrium; it was painless, elastic, fluctuating to the touch; no bosses. Some fever; emaciation. Death occurred September 19, prior to which fever was for some time very pronounced. At the autopsy an oblong tumor twice as large as the child's head was found. Encephaloid cancer. The child had a fall a short time before. (Ollivier.)

Case II., Cancer.—Female aged nine. Was ill about a year, suffering pain in the region of the stomach towards the last. There was vomiting the latter half of the year, with symptoms of marasmus and general anasarca; no jaundice, no albuminuria. Post-mortem: poorly-developed child, very thin; general œdema; primary cancer of liver. (Kottmann.)

Case III., Cancer.—Girl aged fourteen. On December 18, 1881, she was attacked with pleurisy of the right side. The liver was somewhat enlarged. By February, 1882, the pleurisy was cured; two months afterwards the girl became cachectic, with fever. There was marked enlargement of the liver, in which were spots of fluctuation. Puncture evacuated a bloody fluid containing a few lymphoid cells, fibrin threads, and fatty degenerated angular (liver) cells. At the autopsy a widely diffused telangeiectatic cystic cancer of the liver and thrombosis of the inferior vena cava were found. (Henschen.)

Case IV., Encephaloid Cancer.—Boy eleven years old, admitted February 24, 1881. He had enjoyed good health prior to February 12, when he felt pain in upper part of abdomen, especially in hypochondrium, radiating into the back of the left shoulder, with irregular exacerbations; slow digestion, flatulence, and constipation. No injury in hepatic region. For four or five days nose bled seven or eight times a day. When he entered the hospital, he was very thin, cheeks a little colored, eyes brilliant, conjunctiva slightly icteric. Responds clearly to questions put to him, and seems intelligent. He lost much flesh within fifteen days. Skin warm; pulse a little more frequent than normal, 100. Respirations 34. No appetite; no vomiting; no constipation. Abdomen much swollen, noticed by mother five or six days before admission to hospital, and at that time said to have been very hard. Subcutaneous abdominal veins dilated. In the epigastrium below xiphoid, abdominal wall elevated by a tumor extending into right and left hypochondrium and much more prominent at epigastrium and a little to the right of median line between umbilicus and the base of the chest. It seems convex. Distance from xiphoid to umbilicus fourteen centimetres, from left anterior iliac spine twenty-three and from right twenty-one centimetres; circumference of the body at the umbilicus sixty-six centimetres. Palpation meets with resistance at the most prominent part between this point and the costal border, then a small and separate tumor is felt of the size of a little walnut. Liver increased in volume considerably, and its border felt distinctly two or three finger-breadths above umbilicus; no hydatid vibration. February 26, profuse epistaxis. On puncture about fifty grammes of a red liquid withdrawn, only pure blood. March 1, more acute abdominal pain and local peritonitis; pain increased in severity to the 4th. March 6, small hard nipple-shaped tumors felt above four or five finger-breadths above pubis, not movable. They seem to be adherent to the liver, and also constitute the border of it. March 12, liver increasing in volume, pain more and more acute. Epistaxis more and more frequent. Temperature remains about 38° C., but pulse is between 120 and 130, and respirations are 35 to 40 per minute. Cachectic and thin. No vomiting; tendency to constipation. Urine remains scanty; the greatest quantity of urea in twenty-four hours is three and a half grammes. Usually it varied between one and a half and two grammes, and often fell as low as twelve decigrammes. Peritoneal friction disappeared little by little, and abdomen increased in volume. Ascites appeared and became considerable in the last days of the disease. Some signs of bronchitis and a little congestion in the base of the lung were demonstrated. Pain very acute during whole duration of disease. Patient died exhausted March 29. Duration of disease forty-five days.

Autopsy.—Liver very large, extending four or five finger-breadths beyond pubis; large cancerous tumor occupies greater part of right lobe, the edge of which with its bosses had during life been felt above the pubis. Cancer, encephaloid, primary. Liver weighs three kilometres and two hundred and seventy grammes. (Deschamps.)

Case V., Cancer.—Female three years old; no clinical history. Left lobe of liver transformed into a large tumor-mass, extending to upper surface of the right lobe. Surface of the left lobe lumpy; tumor in most places soft. (Wolff, from Birch-Hirschfeld.)

Case VI., Cancer.—Boy of twelve; history unsatisfactory. Tumor situated in right lobe of liver; corresponded with the nodular form of adenoma of the liver, and in some places there is already pronounced change into carcinoma. (Birch-Hirschfeld.)

Case VII., Sarcoma.—Girl twelve years old, sick for four months with pain in liver-region. For one month swelling of abdomen and thoracic region from the right collar-bone to the navel, and at last place a fluctuating prominence. Hydatid diagnosed. On puncture, evacuated bloody serum. Four weeks later death, prior to which pronounced cachexia and œdema of limbs. On section, tumor right lobe of liver occupying whole place on the right side from clavicle to pelvis. Medullary spongy sarcoma. (Roberts, *Lancet*, 1867, i. 3, quoted by Birch-Hirschfeld.)

Case VIII., Sarcoma.—Child aged two and a half years. Presented for treatment in February, 1878. Healthy until Christmas, 1877, when the abdomen became enlarged. The liver was found to be much enlarged. Rapid increase during the next few weeks. Flat, soft, almost fluctuating projections can be distinctly felt upon the liver. Dilatation of veins of abdomen and lower part of thorax, increased emaciation, slight jaundice. Death March 23.

Autopsy.—Liver enlarged threefold, yellow. Contains at the periphery and internally numerous yellowish-white, soft tumors from the size of a hazel-nut to that of a walnut. Gall-bladder dilated; cystic duct compressed by a tumor. All other abdominal organs normal. Other viscera not examined. Medullary sarcoma. (Henoch.)

Case IX., Sarcoma.—Male aged eight months was taken sick with diarrhœa, lost appetite, and became emaciated. When nine months old a solid tumor was noted by mother in abdomen. Profuse diarrhœa continued and child rapidly emaciated. Disease lasted four months. In first six weeks of life the circumference of the abdomen increased from twenty-one to twenty-five inches, while the tumor, with uneven surface, was best felt on the left side. At autopsy left lobe of liver healthy and enlarged; right lobe pressed under ribs, and in it a medullary sarcoma. Separate nodes found in right lung. Other organs healthy. (West.)

Case X., Adenoma.—Boy aged twelve years. "Nothing in history to throw light on case." No evidence of congenital syphilis. Boy stated that three months before admission he fell on his side, after which he noticed a swelling, which sometimes gave him pain.

Symptoms.—General health and general condition good. Occasionally pain over liver and some sickness of stomach. No ascites. He gradually became thinner, and two weeks before death became deeply jaundiced and some œdema arose. Temperature 102°–104° F.; pulse 144; respiration 42. Duration about seventeen months.

Physical Signs.—Liver extended three or four inches below ribs; firm, smooth, and elastic; on puncture, a little blood was drawn, but no pus; no signs of echinococcus. After puncture the swelling decreased and health remained good for several months; then liver gradually increased in size. Superficial veins enlarged. No enlargement of lymphatics. No evidence of organic disease in other organs.

Autopsy.—Extreme jaundice; œdema of legs and scrotum. Abdomen contained some fluid; no peritonitis. Liver enlarged two hundred ounces. Right lobe much enlarged and filled with circumscribed yellow masses, some microscopic, some the size of an orange; nodes on surface. Portal trunk and common bile-duct completely blocked. No parent growth appeared; all appeared coeval. No primary growth in pancreas, duodenum, or bile-ducts; no lymph-glands in fissure of liver or elsewhere enlarged. Spleen enlarged. Other organs normal. Tumor was epithelial in structure. Lungs normal, except in right base, where there was a nodule like a shrunken infarct; this was made up of microscopic malignant nodules, each of which consisted of a fibrous sheath enclosing epithelial cells like those in the liver. The author believes the tumor to be a malignant adenoma. (P. H. Pye-Smith.)

Case XI.—Carcinoma in an infant four months old. Healthy up to a month previous. Parents healthy. Child became fretful, developed diarrhœa, and lost flesh.

Physical Examination.—A swelling in epigastrium the size of a hen's egg. Tumor firm, tender, increasing in size. Belly distended; superficial veins enlarged. Duration one month.

Autopsy.—Liver occupied whole of abdominal cavity above umbilicus. Very little fluid in peritoneal sac. Mesenteric glands not enlarged, and all other viscera normal. Liver weighed forty and one-half ounces; glands in hilum not involved. Both lobes studded with tough, whitish foreign growths. Microscopic examination revealed connective tissue enclosing numerous round cells. (S. J. Gee.)

Case XII.—Diffuse sarcoma in liver of an infant three weeks old. No evidence or history of syphilis in parent. Child was found to have a very large liver, almost filling abdomen; surface of abdomen irregular. Veins distinct. Slight œdema of legs and belly-wall. No ascites. Very little intestinal resonance. Child died when three weeks old.

Autopsy confined to abdomen. Liver weighed thirty-three ounces; dark plum-color, quickly changing to red on exposure. Gall-bladder rudimentary. On section, growths from the size of a millet-seed to that of a walnut were found. Similar growths were found between spleen and left kidney, but not involving either. Other organs healthy. Spleen not enlarged.

Treatment had been mercurial inunctions, which produced no effect.

(Dr. Pye-Smith thought it diffuse intestinal hepatitis; others thought it syphilis.) (R. W. Parker.)

Case XIII.—Cancer of liver in a child eight weeks old. Parents healthy, father forty, mother thirty-six; two healthy children, fourth child an epileptic. Patient well at birth, and health good up to ten days before death, when enlargement of abdomen was noted. This was firm and hard; no sense of fluctuation. Enlargement rapidly increased; veins prominent; no jaundice, no emaciation, no cachexia. Only marked symptom was pain, which caused child to cry out, and which seemed to be increased when child was laid on left side. Urine normal. Stools natural, though green at first.

Autopsy.—No peritonitis. About eight ounces of clot and fluid blood in abdominal cavity. One clot over large mass springing from liver at a point of rupture. Other organs healthy. Liver weighed eleven ounces three hundred and seven grains; measured six inches transverse diameter. No inflammation of capsule, which was smooth. Organ yellow in color. Gall-bladder healthy and passage free. Left lobe was seat of a large round growth which occupied its entire extent. Tissues and mass dark, in places almost black. Committee reports cancer. (Pepper.)

Case XIV.—Encephaloid cancer in a boy aged thirteen years, born in Sweden. No history of cancer in family. Four months previous was kicked on right side below ribs, which caused him to remain in house one month. About two weeks after injury he was seized with vomiting and diarrhœa, which continued throughout. Four months after injury abdomen began to swell. He had measles one year previous, from which he made good recovery.

Symptoms.—Tongue red at tip and edges, brown fur in centre. Eight or ten stools daily, sometimes dark, sometimes light. Temperature normal; pulse 105, small. Rapid loss of flesh and strength, and during last weeks intense pain. Duration about five months.

Physical Examination.—On face, arms, and chest, fine papular eruption, copper-colored and with scaly desquamation. Tumor occupying and filling abdomen, extending into chest and down to pelvis, firm, immovable, not tender, thought to be syphilitic.

Autopsy.—All organs normal except liver. Liver nodulated and doughy to feel. Attached to anterior surface was a large yellowish-white granular mass filling nearly the entire abdomen. Weight six pounds ten ounces (avoirdupois). On section, liver looked like fresh suet. Under microscope an endless variety of cells of all sizes and shapes, together with fatty granules and degenerated hepatic tissue. It was pronounced encephaloid cancer. (J. Lewis.)

Case XV.—Myxo-sarcoma in infant four months old. Mother aged between thirty-five and forty, average health; father died of phthisis. Nothing unusual at birth. Some weeks after birth noticed a swelling in abdomen, and navel protruded, teat-like. No history of specific disease.

Symptoms.—Restlessness, short cough, vomited milk; nursed pretty well, but did not thrive. Lost flesh and strength. Temperature normal. Lungs normal.

Physical Examination.—Abdomen excessively and symmetrically enlarged. Veins prominent. Percussion-dulness extending from xiphoid cartilage to hypogastric region and laterally and posteriorly into lumbar and iliac regions. On palpation, firm, smooth, resisting mass filling entire abdominal cavity, with exception of small space in hypogastric region, where on deep pressure margin could be felt.

Treatment.—Iodide of potassium and calomel to child, under which treatment liver-tumor seemed to diminish slightly in size. Duration about nine or ten weeks.

Autopsy.—Small quantity of fluid in abdomen. Liver filled abdominal cavity; smooth and symmetrical; color mottled, like red Castile soap. Spleen and kidney normal, but mottled. Other organs normal, except lungs, which presented caseous deposit, no amyloid change. Microscope showed it to be myxo-sarcoma. (Meisenbach.)

Case XVI.—Scirrhus in a colored boy aged three months. Three weeks before, he had suffered from vomiting, cough, and dyspepsia. Abdomen swollen. Appetite unimpaired.

Autopsy.—Peritoneum contained a small quantity of fluid. Some evidence of recent inflammation of lesser omentum; mesenteric glands somewhat enlarged. With exception of liver, all organs normal. Liver of natural size, firm, and of good color. On anterior mass of left lobe were three scirrhous masses projecting from surface, which looked like fibro-cartilage. Six other patches were found, varying in size from that of shot to that of a three-cent piece. On under surface there was a conical mass the size of a walnut. Anterior border of right lobe involved to some extent. Microscope showed remarkably distinct scirrhous structure. (S. W. Gross.)

Case XVII.—Adenoma of the liver in a female infant twenty months old,[1] who is said to have suffered for three months with loss of appetite and much swelling of the belly, and since that time to have markedly emaciated.

State on Admission.—Height normal; emaciated; skin pale yellow, relaxed; tongue dry, somewhat coated. Belly much swollen. Right side completely filled with a tumor extending in the mammary line from the sixth rib to the iliac fossa, and in the transverse direction at the level of the navel from the vertebræ to the linea alba. This tumor presents on palpation several elevations from the size of a nut to that of a child's fist, projecting from the level of the liver, which feel soft against the very resisting liver. Palpation of the tumor causes no pain. Circumference of the belly fifty-one centimetres, the skin being traversed by large veins. Percussion-note in the whole extent of the tumor empty. Inguinal glands moderately swollen. In the lungs, except moderately large and fine blowing räles, there are no essential changes. Splenic dulness is increased. Stools dark yellow, mushy. Traces of albumen in the urine. Skin-temperature 99.1° F.; pulse 88. Increasing weakness; complete exhaustion; death on the thirteenth day after admission.

---

[1] Jahresber. des St. Joseph Kinderhospitals für 1883, i. 42.

Autopsy.—Apart from pleuro-pneumonia of the right middle lobe of the lung and from certain unessential changes in the other organs, the liver was found enlarged, weighing sixteen hundred grains. Its surface seemed very knob-like, from the projection of the numerous variously-sized tumors. On cutting into the liver it was discovered that, with the exception of the peripheral parts, it was completely substituted by a very soft yellow tumor mass, sprinkled with red as the result of numerous hemorrhages, this mass being separated from the still resisting liver-tissue by a thin capsule. It was divided again by numerous connective-tissue septa into segments of different sizes, showing that it arose from the confluence of numerous individual tumors. In addition, in the peripheral parts of the organ were numerous pea-sized to more than walnut-sized tumors, which were likewise sharply separated from the liver-substance, and exhibited the same properties as the large tumor. Some of them were so soft that they almost fluctuated. The swollen tumors seemed simple, the larger already traversed by fibrous septa. The scanty remainder of the liver-tissue was very soft, and spotted pale brown and yellow.

Careful microscopic examination of the tumors, conducted by Dr. Weichselbaum, revealed the fact that the new formation described is to be regarded as an atypical liver-cell adenoma, a very rare occurrence, especially in so young a child.

Case XVIII.—Lymphadenoma of liver in a boy of fourteen, who for a month before coming under notice suffered with pain in right hypochondrium and wasting. He noticed a swelling in same region about two weeks before admission. When first admitted he was pale and sallow, but not jaundiced. The liver was enlarged, edge reaching nearly to the umbilicus; there was a large bossy swelling situated between the right costal arch and the umbilicus. The superficial abdominal veins were enlarged and tortuous. By aspiration blood was withdrawn. Wasting; hectic; temperature 98°–102° F. Peritoneum and pleura distended with fluid. Death seven weeks after admission, symptoms having existed for three months.

Autopsy.—Abdominal cavity contained much fluid. Right lobe of liver was much enlarged and contained a hemispherical mass which on section had the appearance and consistence of brain-tissue; some hemorrhage into its substance, and fibrous bands passed through it. It was surrounded by a broad zone of compressed liver-tissue; mass of enlarged glands at fissure. Right pleura full of fluid. On microscopical examination of new growth it was found to resemble structure of lymph-glands. Reporter thinks it started in lymph-glands of fissure and grew into and compressed the liver-tissue. (Ashby and Wright.)

Case XIX., Immense Connective-Tissue Tumor of Liver.—Boy, born prematurely by a few weeks, weighing six pounds nine ounces, and came into the world with a strikingly pale yellow skin and with a swollen belly through which subcutaneous veins showed. Twelve days after birth, when the remains of the umbilical cord had fallen off, some bleeding occurred from the umbilical vein, and subsequently the bleeding recurred repeatedly. The stools during the entire duration of the child's life were blackish brown. In addition there was frequent vomiting of a dark, partly fluid, partly coagulated blood. Œdema of the scrotum, of the penis, and of the lower limbs occurred constantly in a pronounced degree.

Autopsy.—Four weeks after birth. Liver dirty greenish yellow, surprisingly large. Immediately behind the transverse fissure of the liver, corresponding with the Spigelian lobe, was a round fleshy tumor, two and three-sixteenths inches long, one and twelve-sixteenths inches broad, which in part sank into the depths of the parenchyma, and in part projected free of it.

After a full description of the naked-eye and microscopic appearances of the tumor, the author remarks, regarding the origin of it, that most probably it arose from a hemorrhage into the parenchyma of the liver, which occurred without doubt during fœtal life. Careful questioning could not obtain the least foundation for the opinion that it was due to congenital syphilis. (Luschka.)

Case XX., Cyst of the Liver.—Girl eleven years old, admitted May 28, 1886. Well until previous Christmas; then passed ten thread-worms, and belly was noted as large. For three weeks has complained of pain. Tumor increased. Stools always thin and white.

Appetite diminished. Belly much swollen, fluctuating, dull, decided undulation. Palpation shows on left side a firm tumor, which may belong to kidney or to spleen. Liver-dulness over fourth rib; mammary line, therefore, pressed up. Urine normal.

Diagnosis.—Ascites, and probably malignant tumor of kidney.

Operation.—Enormous cyst extending from under surface of liver and filling entire abdomen. No ascites. Cyst removed. In large sac a firm mass of clots or necrotic tissue, which was detected on palpation on left side and mistaken for tumor of kidney or spleen. Patient recovered. There were several small flat cysts in neighboring parts of liver, with milky contents.

The cyst was regarded as a new formation. (C. F. C. Hueter.)

Case XXI., *Lymphadenoma.*—Female aged five. New formation of cystogenic tissue. Was not limited to the liver, but affected the small intestines, peritoneum, and the kidney, so that it is doubtful where it was primary, but clinically the liver-tumor was always in the foreground and it was anatomically the most developed. (Wagner.)

Case XXII., *Diffused Lympho-Sarcoma of Liver.*—Child five years old. Family history good, no hereditary taint. Child's health always good until present illness.

Symptoms.—For six months previous to examination child suffered with anæmia and enlargement of glands in neck. No mention of jaundice or ascites. Lost flesh. From time to time had attacks of diarrhœa and slight hemorrhage from bowels, and just before death repeated epistaxis.

Physical Examination.—Liver extending within one inch of pubis (character of enlargement not noted). She died extremely emaciated. Urine normal.

Autopsy.—Glands of neck and axillæ enlarged. Caseous tubercular masses in both lungs. Spleen and kidneys normal. Abdominal lymphatics slightly enlarged. Liver uniformly enlarged, weight forty-eight ounces; pale and firm; showed no isolated growths; surface smooth, edge not everted. Microscopical examination showed infiltration with small round cells resembling leucocytes and some increase of connective tissue.

Tooth does not think it leukæmia, because the liver was within an inch of pubis two months after anæmia first appeared, and because spleen was not involved. (H. H. Tooth.)

Case XXIII., *Tuberculosis of the Liver.*—Henry Victor, eighteen months old, entered Tenon Hospital, service of M. Gérin-Roze, August 11, 1882. The child had been under the care of Luc in May for a broncho-pneumonia following measles, and was dismissed uncured. In August there were undoubted signs of softening at the apices, followed by excavation. In September the child was seized with diarrhœa, rapidly emaciated, and died September 15.

At the autopsy the lungs were found infiltrated with tubercles; ascites and tuberculosis of peritoneum; tuberculous ulcerations of the mucous membrane of the ileum. The liver (serous surface) presented an eruption of discrete tuberculous granulations. Section (cross) showed a great number of roundish cavities of the size of a lentil, filled with bile. Microscopic examination showed that the cavities were tubercular. The lesions of the liver were not indicated during life by any special symptom. (Henry Luc.)

ABSCESS OF THE LIVER.

Abscess of the liver in children is a comparatively rare affection. The scope of this article will include suppurative inflammation of the liver, and not the general inflammation of the hepatic structure which has been called by various writers hepatitis. Much confusion exists, however, in literature from the use of this term indiscriminately. Descroizilles includes in the article on hepatitis among other varieties a diffused inflammation of the liver, a suppurative inflammation, secondary to enteritis, and another the anatomical appearance of which is the same as that of the liver in new-born infants who die of jaundice. Many writers follow him in this classification, and speak of abscess in the new-born affected with jaundice as most common.

Baumes particularly refers to this, and Bouchut speaks of malignant hepatitis of the new-born, several cases of which he had seen with abscess. Burton quotes Baumes, but confirms the statement of Denis. The latter says that in numerous autopsies he has not confirmed the real existence of this lesion. Bouchut says that one-third of new-born children have hepatitis which until the time of his writing (1867) had been described under the name of jaundice. The title of his article is Hepatitis, which he divides into the simple, malignant, chronic, and traumatic forms. The simple form is the common icterus of the new-born. The malignant form, or icterus gravis, is the variety which Baumes and Martin of Lyons refer to, in which small abscesses were found in the liver. By the chronic form he apparently means hypertrophic or syphilitic cirrhosis. The traumatic variety includes abscess of the liver as we are about to consider it. He quotes the case of Renaud, which we have included in our table, as an example of this variety of hepatitis. Fabre declares that one of the above-mentioned writers, Baumes, made the diagnosis of abscess during life, but did not confirm it by an autopsy. He doubts the existence of abscess of the liver.

The following remarks on abscess of the liver are based upon an analytical study of thirty-four cases of this affection collected from the literature of this disease. The writer is indebted to the article of Bernhard on abscess of the liver in children for much valuable information. It is the most exhaustive paper that has been presented on this subject. It includes an account of three cases, and a critical study of thirteen more reported by different observers. The systematic article of Birch-Hirschfeld in Gerhardt's Hand-Book contains also much valuable information.

Bertrand first speaks of the rarity of abscess of the liver in children, describes abscess of the liver in the new-born, and then studies the collected cases of suppurative inflammation of the liver. He thinks, first, that the child's organism of itself is less disposed to suppurative inflammation of the liver than that of adults; second, that nearly all the etiological factors which lead to this disease in adults may also be effective in children, except those arising from diseases of the bile-ducts. His conclusions regarding the symptoms will be given under that heading in this article, as well as his remarks on the diagnosis. Birch-Hirschfeld considers abscess of the liver to be due to four general causes: first, contusions; second, metastasis or pyæmia; third, tropical causes; fourth, irritation of worms.

After a consideration of the frequency of abscess of the liver in children as first discussed by various authorities, we will consider the subject in a systematic manner.

Frequency.—As intimated above, it has been considered rare in children. Rouis speaks of its prevalence in Algiers: of two hundred and fifty-two persons with abscess of the liver, he found only one less than twelve years old; the next in age was a French soldier eighteen years old. Unfortunately, the histories of these cases are not given. Annesley, in his work on the diseases of India, states that the drummer-boys in the

English army rarely, if ever, develop abscess of the liver. Bernhard refers to the association of abscess of the liver in adults with typhlitis and perityphlitis as the most common form seen in Germany, but no such case has hitherto been reported as occurring in a child, and, in general, cases are extremely rare in which the abscess follows pylephlebitis. Cheevers, in his "Commentary on the Diseases of India," writes exhaustively of abscess of the liver, and states that he has never seen hepatitis or liver-abscess in childhood, and that in the four years ending 1883 there occurred among the soldiers' children throughout India a total of thirteen cases of hepatitis with only one death. He further observes that hepatic abscess, presumably idiopathic, when it occurs in very early life is probably of tubercular origin. Morehead showed that the ratio of hepatitis in children was, when he wrote (1860), in "Bengal 0.05 and in Madras 0.3 of strength." He cited the returns of the Byculla schools as proving the rarity of the disease. In Bombay, at the same time of life, the admissions in seventeen years were nine, with one death, out of from two hundred and fifty to three hundred children. Surgeon-General Macpherson for the four years ending 1853 shows that one-twentieth of one per cent. of the soldiers' children had acute inflammation of the liver, with no death. Cheevers could only find accounts of three cases of hepatic abscess in children : first, a child of seventeen months ; second, a European child of three years and four months ; third, a Parsee child of ten years. Blaney in the statistics of diseases treated at the Bombay European General Hospital, published by Morehead and Stovell, was unable to find a single case of hepatitis in a child. Waring, in a table of two hundred and twenty-seven cases, noted the occurrence of liver-abscess only after the sixteenth year, never having seen a case under that period. Murchison, Frerichs, and others corroborate this observation. We have been able to collect thirty-four cases under fifteen years.

Abscess in the New-Born.—This has been previously referred to and the opinions of some authors quoted. While by some it is thought to be very prevalent, others doubt its existence. Mildner in two hundred sections found inflammation of the umbilical vein forty-six times, thirteen times with phlebitis alone and fourteen times with phlebitis and arteritis of the umbilical vessels. Bernhard thinks that the latter is more frequent than the former when it arises from infection of the navel. Hennig believes that the danger of thrombosis and embolism of the umbilical vein is greatly over-estimated, because the vein of all the fœtal passages is the first to dry up and not rarely is narrowed at birth. He thinks that softened thrombi are only rarely introduced through the ductus venosus into the vena cava. He believes the presence of thrombi at the point of issue in the umbilical vein into the portal vein occurring so frequently and singly is proof of the, for the most part, autochthonous origin of liver-abscess. Hecker and Buhl do not share this opinion (Mildner). Bouchut mentions the previously noted observations of Baumes and others, who observed several cases of multiple suppuration in the liver, partly with and partly without abscess-formation. Birch-Hirschfeld found miliary abscess in the liver four times in four hundred and ten autopsies upon new-born children. Ritchie describes a case of liver-abscess holding about one and a half ounces of pus. The abscess was on the lower surface of the liver, principally on the right lobe; the umbilical vein was involved. Kraschutzky reports thirteen cases of inflammation of the umbilical vessels without changes in the liver. Runge reports forty cases with nineteen autopsies without changes in the liver, and in all of the nineteen cases the umbilical artery was diseased.

It appears, therefore, that from infection of the navel the new-born child may have inflammation of the umbilical vein and of the umbilical artery, separately or combined, and that only in a very small proportion of these cases abscess of the liver may occur. The writer saw a case of umbilical arteritis in an infant who died on the tenth day after its birth. The cord bled several times, requiring frequent ligatures, which were done by an unclean midwife. The child was ill, but no systemic symptoms save fever were observed until the fourth day after birth, when a light jaundice supervened. On the sixth day the metatarso-phalangeal joint of the index finger became inflamed. The elbow-joint of the same side, the right, was also seen to be inflamed within twenty-four hours. The child died on the tenth day, of convulsions, apparently due to high temperature. At the autopsy suppurative inflammation of the joints, and inflammation and suppuration of the umbilical artery, were found. The heart, liver, and lungs were normal.

Etiology.—Of the thirty-four cases of abscess of the liver under fifteen years which we have analyzed, the youngest child was one year old. The average age was a little over nine years. Of the thirty-three cases in which the sex was given, fifteen were girls and eighteen boys. Age and sex have no etiological value. The most frequent cause assigned is injury, which was observed in eight cases. In some the causative influence of injury is doubtful, and in others it may have been assumed in the absence of a cause that could be definitely demonstrated. In Starr's case two causes may have been operative,—either injury or round-worms. The next most frequent cause of the tabulated cases appears to be round-worms which have wandered from the small intestine into the bile-ducts and thence set up inflammation of the liver. In seven cases they were undoubtedly the cause, and in one (Starr's) they were a possible cause. In the remaining eighteen cases the abscess appears to have arisen secondarily to a pylephlebitis in four cases, to an umbilical phlebitis once, while twice it was pyæmic, and once each it was secondary to pelvic peritonitis, dysentery, perityphlitis, malarial fever, and tuberculosis of the lungs. In six of the cases the cause is not stated. It is thus seen in this series of cases, collected from the literature of the German, French, English, and American writers on this subject, and hence from cases in many countries, that the general conditions which appear to be so influential in certain countries in the development of abscess of the liver in adults do not obtain in children. Atmospheric influence, temperature, climate, and habits of life need not therefore be considered as etiological factors in abscess of this time of life.

Of the traumatic cases we find a fall striking on the right side, a blow with the fist, or a fall upon a sharp corner of a chair as the direct cause of the inflammation. In one case (31) a boy was lying upon his abdomen on a sled, when another boy fell on him. Suppurative inflammation of the liver developed shortly afterwards. The occurrence of ascarides as a cause is of interest, and its frequency is particularly noticeable. In two cases indicated their association was doubtful. They had been found in the intestinal canal after death or were passed by the rectum during the illness, and, as no other cause existed, the attending physician thought their presence sufficient explanation of the cause of the inflammation. In the instances in which they have been noted as positive factors (12, 13, 14, 15, 25) they were found in the abscess or the liver-structure after death. They had given rise during life to no symptoms which would have caused their presence to be suspected.

The cases following pylephlebitis were due to portal emboli, and in their origin and mode of development were similar to such cases in adults. In one the pylephlebitis was secondary to perityphlitis; in one it apparently followed typhoid fever. In the pyæmic cases, so called, pelvic peritonitis preceded the vein-inflammation in one, rupture of the vermiform appendix in another, and an abscess on the left hip in the third. Dysentery preceded the abscess in one case only (2). A history of exposure to malaria in Africa, without other obvious reason, makes it probable that the same influences that operate in adults to produce tropical abscess were the cause of the suppuration in this rare case. Diarrhœa continued during the two weeks prior to the development of the local symptoms in the case of Dulles, but it cannot be said whether it bore any causal relation. The primary abscess could not be ascertained in Legg's case, but numerous abscesses were seen at the autopsy throughout the abdominal cavity, and the scar of a healed abscess was observed on the upper surface of the right lobe of the liver. The case of umbilical phlebitis is obscure, although the possible primary abscess was in the thymus gland. The case which presented during life the symptoms of phthisis only (33) is also of obscure origin. It had been referred to by Berton as one of tubercle of the liver, a condition scarcely possible.

The case that followed typhoid fever (27) is worthy of further notice, on account of the rarity of such a sequel either in childhood or in adult life. The intestinal ulceration had healed, but the glands, which are frequently affected in typhoid, had suppurated and primarily infected the portal vein.

Symptomatology.—The symptoms of abscess of the liver are almost always, and particularly in the pyæmic, or metastatic, form, associated with the symptoms of the primary disease, and hence are often masked by them. Indeed, the mode of onset, the progress, and the duration depend largely upon the cause of the inflammation. If, in cases the symptoms of which indicate local purulent inflammation in the portal area, pain arises in the liver region, increased by pressure, and especially if this is associated with the development of a painful tumor, which presents the physical characters of an abscess, in all probability the liver has become secondarily infected.

In the traumatic forms, of which six examples are given, either the symptoms developed within a few days after the receipt of the injury, or any inflammatory process was quiescent and without local symptoms for several days or weeks. In one case (16), after a fall, in which the right side was struck, there were no symptoms until a tumor was detected six weeks subsequently. In another, after a blow, pain and other inflammatory symptoms developed immediately, and on the fourth day jaundice. In another (18), the fall took place four weeks before the symptoms arose. In one (30), the injury took place in August, and in October the patient began to complain of hectic symptoms, indicating the presence of pus. So, too, in another (1), the fall occurred months previous to development of the symptoms. The long interval between the injury and the local symptoms is not incompatible with our knowledge of the occurrence of inflammation and suppuration in other portions of the body after injury.

The symptoms associated with the presence of ascarides as cause possibly more distinctly simulate the mode of development of a tropical abscess of the liver, particularly if single, than when the abscess arises from other causes. Under these circumstances it is less related to diseases in other portions of the body, is less complicated, and hence its evolution can be studied more readily. In the case of Lebert (13), the patient was taken sick with chill and fever, followed by pain in the right portion of the belly, and attended by diarrhœa. The liver increased in size and became painful, and later pulmonary symptoms, from extension of the abscess, developed. In another (14), after the occurrence of diarrhœa and vomiting in January, the abdomen increased in size, and by March was very tense and sensitive to the slightest pressure, especially over the liver. In another seemingly typical case of single abscess (12), slight fever, abdominal pain, more or less constant, with cramps in the bowels, continued for six weeks. One week later pleurisy of the left side, and five weeks later pleurisy of the right side, with effusion, took place. In still another (11), an attack of pleurisy took place, followed by effusion and attended by remittent fever. No hepatic symptoms were observed, but, on aspiration, serum was drawn from the chest, and pus from what appeared to be a liver-abscess. Prior to death œdema of the right face, eyelid, thorax, and arm occurred.

The case of Bluff (15), in which the abscess was believed to be due to ascarides, continued over a long period of time, and presented symptoms characteristic of these cases of long duration,—intermittent fever, which continued for three months, followed by pain in the epigastrium, gradual enlargement of the abdomen, and subsequently the formation of a fluctuating abscess at the navel which contained "liver-pus."

The case secondary to pelvic peritonitis (32) indicates strikingly the mode of onset of a suppuration in the upper half of the abdomen, presumably of hepatic origin, and the formation of an abscess not from pylephlebitis, but from contiguity of structure. The chill and high fever, the rapid pulse, the painful and shallow respiration, the development of a bulging over the liver, which previously had been tender, without the occurrence of jaundice, indicated clearly the presence of hepatic abscess, and showed the mode of onset of a possible idiopathic or solitary hepatic abscess. The case of Mall (10) is a rare one. Characteristic chills followed by violent pain over the liver, the occurrence of febrile symptoms and of vomiting, together with light jaundice, enlarged and prominent liver, and a tumor in the right hypochondrium, clearly indicated hepatic abscess, although no cause for it could be ascertained.

A similar case of rapid course is that of Easmon, the origin of which could not be ascertained, although it was probably similar to the tropical abscess.

The study of the individual symptoms of abscess in children reveals some points of considerable interest. In the cases which we have analyzed, pain, enlargement of the liver, the presence of a tumor, fever, with or without chills, gastro-intestinal and pulmonary symptoms, are those of most frequent occurrence. These symptoms are both local and general.

Pain.—In the tabulated cases, pain or tenderness over the liver was mentioned twenty times, although it is probably present in greater or less degree in every case. It was usually seated in the right hypochondrium or liver region (fifteen cases). In five cases the pain was abdominal, being described as occurring in the cæcal region, in the belly, in the bowels, at the epigastrium, and about the umbilicus. In the traumatic cases, of course, it was the most constant symptom, was more or less violent, and was always increased by pressure. In two instances it extended to, or was only noticed in, the right shoulder.

Enlargement of the Liver.—The liver was enlarged in twelve cases, and in all instances the enlargement was downward. With the enlargement there was also sensitiveness on pressure and generally the occurrence of a distinct tumor.

Tumor.—The presence of a tumor was distinctly mentioned in nine cases, the character not being noteworthy; and swelling in the right hypochondrium or belly in ten cases. In most instances the tumor was located as just indicated. In one (Renaud's) it appeared as a round, fluctuating, and pulsating tumor, over which the abdominal wall was gangrenous. In another (27), an elastic tumor at the lower edge of the ribs of the right side, non-fluctuating, was described. In another, a small painful elevation could be detected on the anterior surface of the liver, which was double the normal size. In another it was simply noted as being found in the right side of the abdomen. In Dulles's case (12) the tumor developed at the edge of the ribs eleven days after the symptoms began, and was fluctuating. In another, a few days after the liver was found to be enlarged, two tumors the size of goose-eggs were detected on its surface. In Legg's case (23) the abscess was located between the umbilicus and the epigastrium. In Wendroth's case there was a tumor the size of a hen's egg in the right hypochondrium.

The cases due to ascarides, curiously, were not attended with the development of localized tumor. In all of them the notes state simply that the liver was enlarged or the abdomen swollen. Nearly all the traumatic cases were attended by tumor-formation. In Case 1, there was a tumor in the right hypochondrium, with bulging of the ribs, but no fluctuation. In Sheets's case the tumor appeared in the right side in the lower part of the chest, and in Drechsler's case a hard swelling the size of a hen's egg was detected in the hepatic region.

The pyæmic cases were usually attended by the presence of a tumor, while in some instances two or three tumors were detected. In each of the three cases of pylephlebitis a tumor existed. In character the tumors were not unlike those of abscess-formation in other regions. In a considerable number of instances fluctuation could not be elicited, but the reason for this is obvious. The development of the tumor was usually gradual, and took place at variable intervals after the occurrence of pain and other local phenomena, and sometimes a long time after the probable cause of the disease.

Fever.—Just as pain was mentioned only twenty times in the series of tabulated cases, although it is probably present in greater or less degree in all cases, so fever was noted or its existence implied in twenty-four cases only. In nearly all the fever was of the hectic, pyæmic, or intermitting type, and was usually accompanied with chills. Sometimes the initial chill alone occurred in the course of the disease; again, and indeed frequently, irregular daily chills took place. The cause of the suppuration did not influence the character of the fever. It was as markedly intermitting in the traumatic as in the metastatic variety.

Often the temperature at night would be as high as 104°–105° F., but in a few instances slight fever only was said to be present. Most characteristic was the occurrence of sweats, usually with the chills and febrile paroxysms: they were extremely profuse and exhausting.

Gastro-Intestinal Symptoms.—The coated tongue and loss of appetite of the inflammatory process were usually present, as would be expected. Vomiting, however, was a more frequent gastric complication than is commonly supposed. It did not occur at any special stage of the disease. It is noteworthy that it did not occur in the pyæmic forms nor in the varieties associated with pylephlebitis, nor did it assume any particular characters.

Diarrhœa was also of frequent occurrence, and it, too, did not arise in the pyæmic varieties of suppuration. In eight of the thirty-four cases it was a marked symptom. An enteritis or entero-colitis was associated with the hepatic abscess in some cases, as the discharges were mucous, muco-purulent, or bloody. Five of the eight cases in which diarrhœa was a marked symptom were associated with ascarides, which were believed to be the cause of the hepatic suppuration.

Constipation was said to have occurred in a number of cases, but it is without significance.

In the cases due to ascarides these parasites were in several instances found in the stools and in the vomited matter.

Jaundice.—Jaundice is not looked upon as a common symptom in hepatic abscess. It was mentioned in six cases. In two cases of traumatic and two of pyæmic origin, and in two the causes of which were uncertain, it occurred in a slight form (9), or was general (29), or was without special description. The occurrence of jaundice depends upon compression or catarrhal inflammation of the gall-ducts.

Pulmonary Symptoms.—In eight cases symptoms due to extension of inflammation to the adjacent respiratory organs were recorded. Pleurisy was most frequent. Pneumonia occurred in one case, and pneumothorax in another.

Naturally, short and interrupted breathing, on account of pain on respiratory movement, occurs, while a short hacking cough often is most persistent. In five of the cases of hepatic abscess caused by round-worms, pulmonary symptoms were most marked, while in all the other cases combined this complication occurred only three times. In one case pleurisy developed because of rupture of the abscess into the pleura; but in the other cases the pulmonary symptoms arose from extension of inflammation by continuity of structure.

Miscellaneous Symptoms.—It is almost needless to say that loss of flesh and strength took place in a number of cases. Cerebral symptoms—convulsions, delirium, and stupor—also occurred during the course of the disease in a few instances. The high temperature was believed to be the cause of these phenomena. Hiccough, due to inflammation of the diaphragm, may occur, although it is not recorded in any cases of hepatic abscess in children. The position which the patient assumes is spoken of in accounts of the disease in adults. No particular note has been made of the decubitus in children. The same may be said of the appearance of the countenance, said to be quite characteristic in tropical abscess of adults (Cheever).

Complications.—The complications are due to the nature of the primary disease, when the abscess is metastatic; or to inflammation of the organs adjacent to the liver, either by contiguity or because of the direction in which the abscess tends to discharge. Acute endocarditis was associated with a case of pyæmic origin (25). Pleurisy and peritonitis are occasional attendants. In three cases of the thirty-four tabulated the former occurred, and in four the latter. It is quite certain that the bursting of the abscess into cavities or into other viscera does not occur in children so frequently as in adults. The accident occurred once (13) in the tabulated cases.

Duration and Issue.—Only an approximation of the duration of the disease can be arrived at. In the series we have analyzed the average duration is about six weeks. In nine cases it appeared to range from seven to forty days, and in four, from three to eleven months.

In all forms the duration was variable. This is especially true of the pyæmic varieties. Birch-Hirschfeld remarks that idiopathic abscess usually results in death at the end of a few weeks, but at times is subacute, and not rarely runs a chronic course, even lasting a year. We cannot confirm the latter portion of the statement from the collected facts.

The duration of the traumatic cases varied also. Löschner's second case (17) died thirteen days after the injury, Renaud's[1] little patient died seventeen days after, and Constant's died in the seventh week.

In cases in which recovery occurs, all symptoms disappear in at least eight weeks (Mall's case).

The issue was favorable in twelve of the thirty-four cases. Operative treatment contributed largely to the favorable termination, for of thirteen cases that were submitted to some form of operation, eleven recovered, unaided nature alone being credited with the recovery of one out of the twelve.

The cases that terminated in recovery were of traumatic origin, or arose from the irritation of worms. The abscess, in other words, was single, or at least not more than two abscesses were present.

Prognosis.—The prognosis is not more favorable than in adults. The recent developments in operative measures for the relief of abdominal disease, and the success which Tait, Mayo Robinson, Thornton, and others have met with in dealing with the surgery of the liver, encourage the belief that death from single abscess of the liver will be the exception in the future.

Notwithstanding the observation of Birch-Hirschfeld, that the traumatic cases (three) which he analyzed ended fatally, we believe success will uniformly attend operations for these cases. Thierfelder collected, from the literature of the last thirty years, twelve cases of traumatic hepatitis, with seven recoveries.

Hepatic abscess secondary to pylephlebitis is often fatal, and when of pyæmic origin it is always so.

Morbid Anatomy.—Space need not be taken up with a discussion of the anatomical appearances of hepatic abscess in children. They do not differ from the appearances in adults. It may be of interest to note only the relative frequency and association of the multiple and the solitary abscess as seen in children. Briefly, it may be said that a single abscess was found in all the traumatic cases (eight) of the tabulated list, one—or at most two—in the cases due to ascarides (eight), and one in the cases of pylephlebitis. Multiple abscesses (three or more in number) were found in thirteen cases.

The morbid anatomy of the antecedent and associated pathological changes is well known.

Diagnosis.—We are concerned in the early detection of hepatic abscess, in the recognition, for the purpose of treatment, of the special variety of inflammation, and in the estimation of the presence of the grave associated inflammations of surrounding structures. Suppuration of the liver must not be confounded with other affections of that organ, notably cancer and hydatid disease, or with abscess of the surrounding viscera, and particularly with abscess between the liver and the diaphragm.

---

[1] Birch-Hirschfeld erroneously states that in Renaud's case the course of the disease was from March 27, 1850, to January 17, 1851.

In the recognition of abscess of the liver in childhood, we can frequently associate some definite cause with the suspected inflammation. The progress of subsequent events, with a study of the symptoms collectively rather than individually, aids us in our judgment.

Thus, if in the presence of trauma, or of inflammation and suppuration in other parts of the body, there occurs pain in the region of the liver, with a sensation of weight and fulness, with tenderness on pressure, with a chill or chills followed by fever, with loss of appetite, vomiting, and possibly diarrhœa, we have strong reasons for suspecting the formation of an hepatic abscess. If later the fever assumes a pyæmic or hectic type, with chills, sweats, exhaustion, emaciation, and the local signs of suppuration, our suspicions are confirmed. The occurrence of jaundice, if the cause is probably pyæmic, is a strong affirmative rational symptom. The short duration of the disease is of diagnostic value.

Of the physical signs, enlargement of the liver uniformly, or upward anteriorly; bulging of the ribs; the formation of a tumor in the epigastrium or right hypochondrium connected with the liver; fluctuation of the tumor; and œdema of the skin, or even inflammation of its surface, are to be looked for. It is to be remembered that a large abscess may be present and yet not be demonstrable by physical means.

The use of the exploring needle or aspirator has been referred to in the account of the symptoms. In a suspected case it can be employed. Often by it alone can pus be located. Fenwick relies much for diagnosis on the microscopical characters of the fluid withdrawn, and believes that nearly always hepatic tissue can be recognized in the purulent fluid. His sanguine expectations, however, do not appear to have been confirmed.

By means of exploratory puncture a hydatid tumor can be recognized or the presence of carcinoma determined. Its value in pleural effusions has been dwelt upon already.

Hydatid disease of the liver can be distinguished from abscess by attention to the following phenomena of the former: the long duration of the disease, the absence of pain and of constitutional symptoms, and the peculiar circumstances of its occurrence. A local projection from the general contour of the liver occurs in both; the aspirator reveals the difference in the contents of a tumor. The tumor of abscess has indurated tissue around it, and local inflammation is more likely to be evident on the surface. The characters of a suppurating hydatid cyst and multiple echinococcus have been discussed (p. 445 *et seq.*).

Cancer and abscess of the liver in childhood have symptoms and signs in common. Both are of short duration, both cause enlargement of the liver, and in both fluctuating tumors are observed. In cancer the liver is of larger size, and more nodules, possibly fluctuating, are detected, but none of them are as painful as the fluctuating projections of an abscess. The abdomen is more increased in size, and the abdominal veins more distinct, in cancer than in abscess. Cachexia attends the former; active constitutional symptoms (hectic) more frequently attend the latter.

The association of pleural effusion or empyema with abscess of the liver frequently makes it difficult to recognize the presence of the latter. The results of percussion, as indicated in a previous section, are important aids to the distinction of hepatic abscess. Bernhard says that in liver-abscess complicated with pleural effusion the limits of dulness can rise higher anteriorly than posteriorly, and, in general, are irregular.

Puncture, with antiseptic precautions, may lead to a diagnosis. Thus, in the upper intercostal spaces, which are dull on percussion, a serous fluid may be withdrawn, and in the lower, pus. Or, if the trocar is plunged deeply, at first it may give exit to pus, but, as it is withdrawn from the abscess to the level of the pleural exudate, serum may be discharged. It is more difficult to differentiate the two conditions when pus is both above and below the diaphragm. The history of the case may be the only method of distinction.

The distinction between pleuritic and pulmonary inflammation and hepatic suppuration has been referred to in discussing the pulmonary symptoms of abscess of the liver, as well as in the preliminary remarks on enlargement of the liver in general. It must not be forgotten that pus from an empyema, if it communicates with a bronchus, is most fetid when evacuated by trocar, and that during such evacuation air may pass through the canula.

Can we distinguish the various forms of hepatic abscess? Multiple abscesses are not amenable to surgical treatment, while many other forms are. The importance of an attempt at the formation of a distinction is apparent.

Traumatic abscess has well-defined symptoms. Local pain, local physical signs of suppuration, enlargement of the liver, and constitutional symptoms clearly show its presence after an injury.

If suppuration is known to be present in the portal area, and the symptoms enumerated above—especially chills and intermittent fever—arise, pylephlebitis and hepatic abscess are likely to be present. In the tabulated cases gastro-intestinal symptoms were absent in the cases due to pylephlebitis.

Davaine[1] writes of six cases in which ascarides caused abscess of the liver, two of which were in children. The most important symptoms of this affection of the liver, he says, are fever, more or less acute pain in the right hypochondrium, icterus, convulsions, vomiting, and diarrhœa. In the cases we have tabulated the detection of the worms by vomiting or purging was noted several times. The occurrence of such vomiting in the course of suspected hepatic abscess would warrant the belief that an abscess from the irritation due to the worms was in progress.

---

[1] Traité des Entozoaires, pp. 156–175.

The importance of this aspect of the study of abscess of the liver in childhood has led us to make a comparative study of the symptoms in order to determine, if possible, a means for detecting the different forms. Practically, the traumatic variety and that due to worms could be associated. They alone cause single abscesses. We have, however, divided the thirty-four cases according to cause into four classes,—*i.e.*, cases from (i.) injury (eight), (ii.) worms (eight), (iii.) pyæmia or metastasis (four), and (iv.) miscellaneous. The cases are too few for definite purpose, but some interesting facts have been developed. Only the prominent symptoms are discussed. The Roman numerals above associated with the causes will serve to designate the classes. In some cases the record of symptoms is not complete, hence the analysis is not beyond criticism.

1. Fever: in i., eight times; ii., five times; iii., four times; iv., four times. No particular type was associated with the particular cause.

2. Pain: in i., eight times; ii., twice; iii., once; iv., six times. Pain was characteristic of the traumatic form.

3. Enlarged liver: in i., three times; ii., four times; iii., four times; iv., three times. It was more common with ascarides and in miscellaneous forms.

4. Tumor: in i., twice; ii., twice; iii., five times (?); iv., four times Singularly, less common in the traumatic form.

5. Gastro-intestinal symptoms: in i., vomiting twice, constipation twice; ii., diarrhœa five times, vomiting twice; iii., absent; iv., diarrhœa twice, vomiting once. The great frequency of diarrhœa with ascarides appears to be significant.

6. Jaundice occurred twice in i., iii., and iv., and was absent in ii. Its presence, therefore, was not of much significance.

In the preliminary remarks it was noted that abscess of the abdominal walls and abscess between the liver and the diaphragm simulated abscess of the liver. The distinctions were discussed. To distinguish subdiaphragmatic and hepatic abscess is most difficult,—indeed, well-nigh impossible. The cause of the former Fagge lays stress upon, as of diagnostic value,—namely, direct injury. Both Fagge and Taylor[1] detail interesting cases of abscess between the liver and the diaphragm in children.[2] These abscesses cause the same local symptoms and local signs, have the same associated inflammation of adjacent structures, and burrow in the same way, as hepatic abscess.

---

[1] Guy's Hospital Reports, Third Series, vol. xix., 1874.

[2] Fagge has collected sixteen such cases, and Frederick Taylor has reported two more. One of Fagge's cases, and both of Taylor's, occurred in children. It would appear from these that the cause is generally a traumatism, and that pleurisy, empyema, pneumonia, and bronchitis, with or without expectoration of blood and pus, are more common than in abscess of the liver. Symptoms of peritonitis are also more pronounced in the former, while symptoms and physical signs, including jaundice, directly referable to the liver are fewer and less precise than in abscess of the liver. The typical physical sign of the latter disease, a rounded, fluctuating, painful, and tender tumor situated in the liver-substance, of course does not exist in the former.

Treatment.—The occurrence of twelve recoveries in the thirty-four cases tabulated, in eleven of which operative measures of some sort were resorted to, establishes beyond further discussion the method of treatment to be pursued in cases of abscess of the liver. It is not necessary to reiterate the dangers of non-interference nor to answer the objections against an operation. The table shows that without an operation the patient almost invariably will die. Aspiration or incision, or both, were the means employed to evacuate the abscess.

The cases that Murchison, revised by Brunton, indicates should be operated on are, (1) those in which there is a visible fluctuating tumor; (2), cases with symptoms of hepatic abscess with a distinct tumor; (3), cases with symptoms of abscess with enlargement of the liver and local œdema, or obliteration of an intercostal space, or local pain on pressure or on full inspiration; explore with a fine trocar, and operate if pus is obtained; (4) even without local signs, severe constitutional symptoms warrant exploration with the aspirator; (5) in multiple abscess of the liver, life may be prolonged and suffering relieved by puncture.

Regarding the surgical treatment of hepatic abscesses it may be of interest to note the conclusions reached by Mr. Rickman J. Godlee.[1]

Having decided to relieve the patient,—such decision being based on the exclusion of multiple hepatic abscess, for the relief of which operative measures are scarcely advisable,—the question arises as to the time at which the operation should be performed, and the method of operating. The operation should be performed as soon as pus is known to be present. It may be done by free incision, or by aspiration with a large canula.[2] Free incision, with antiseptic precautions and the introduction of a drainage-tube, appears to be the best and speediest method of treatment. It is not necessary to cause, artificially, adhesions between the liver and the thoracic or abdominal wall. The peritoneum and liver-substance may be stitched together. Tiffany, of Baltimore, successfully evacuated an abscess in this manner.

Before pus has been detected or the exact location of the abscess decided upon, the patient must be treated by local applications, as hot fomentations or poultices, nourishing—preferably liquid—food given, and tonics and stimulants resorted to. Pain must be relieved by opiates, and other symptoms treated as they arise. In general, proper diet, tonics and stimulants, and opiates *pro re nata* meet all the indications, outside of the relief the surgeon can afford.

TABLE.

No.	Reporter.	Reference.	Age.	Sex.	Cause and Symptoms.	Result, Course, Treatment.	Remarks.
1	Obre.	Trans. Path. Soc. Lond., iii. 115.	9	F.	Possibly *traumatic*, from a fall some months previous, not followed by any indications of severe injury. Hectic, pulse 90–140, œdema right leg, convulsive movements right leg, no jaundice. Swelling in right hypochondrium, bulging ribs, no fluctuation.	*Death.* Aspiration; abscess opened, but opening allowed to close; tumor enlarged, hectic; death eleven days after fulness in side was first noticed.	Cavity containing one and a half pints of pus in right lobe. Pneumonia at right base. No ulceration in bowel. Gall-bladder normal.
2	Moore, N.	Trans. Path. Soc. Lond., xxxii. 132.	3½	F.	*Dysentery.* Had had diarrhœa for a year; last two months stools slimy and bloody. In hospital five weeks. Had always lived in London.	*Death.*	
3	Ritchie, R. P.	Edin. Med. Jour., xiii. 181.	1⅚	F.	*Umbilical Phlebitis.* For two or three days, ill with vomiting and diarrhœa; stools slimy and yellow. Skin sallow; papular syphilitic eruption.	*Death*, in sixteen days.	Abscess of thymus. Single abscess in right lobe of liver at entrance of umbilical vein. General peritonitis.
4	Fergus, W.	Lancet, 1884, i. 1182.	15	M.	Probable *perityphlitis.* Of tuberculous family. Aspect sickly; tongue heavily coated, thirst, dryness of mouth; fever, 104.5° F.; urine normal, except abundance of lithates. Stools from two to four a day; no jaundice; frequent perspirations and rigors. Abdomen swollen. Liver enlarged. Pain chiefly in cæcal region.	*Death.*	General peritonitis. Abscess two-thirds the bulk of the liver. Condition of cæcum not mentioned.
5	Easmon, J. F.	Lancet, 1887, ii. 310.	3½	F.	*Malarial.* Patient lived in Gold Coast Colony, Africa. Swelling noted three weeks after bilious malarial fever. Rapid loss of flesh and vomiting. Large tense tumor occupying right hypochondrium.	*Recovery*, after several aspirations.	
6	West, S.	Med. Press and Circ., 1884, xxxvii. 277.	11	M.	———. Never lived out of London. Rigor followed by pain in right hypochondrium. Extremely ill. Temperature, 105° F. No physical signs mentioned.	*Recovery.* One month from onset, large abscess aspirated. Four days later, incision, second abscess opened. Two weeks later, last two abscesses again	Convalescence retarded by abscess of abdominal wall, which was opened.

						opened and drained. One month later, fresh abscess discovered and opened. Duration about three months.	
7	Miller, H.	Trans. Med. and Phys. Soc. Bombay, 1849–50, 313.	10	M.	——. Parsee boy, born in India. Twenty-four days before he was seen he was seized with pain in right side, accompanied by continued fever. Thirst, bowels constipated, urine scanty and high colored. Liver much enlarged, distinct fluctuation over anterior surface of right lobe.	*Recovery.* Abscess incised on twenty-fifth day. Pus continued to discharge for one month. Patient then discharged well. Duration about eight weeks.	
8	Starr, L.	Trans. Coll. Phys. Phila., 1876, iii. 17.	5	M.	Possibly *traumatic*, possibly from *round-worms.* Lived in a malarious district. Well up to one week before admission. Pain about umbilicus. Castor oil brought away from twenty to thirty round-worms. Restlessness; some fever; no jaundice; bowels moved daily, passage hard and small. Swelling of abdomen, later tenderness and deep-seated fluctuation.	*Recovery.* Poultices followed by aspiration. Duration eight weeks.	
9	Vogler, G. W.	Jour. Amer. Med. Assoc., 1887, viii. 275.	12	F.	Apparently *traumatic*, from pressure and strain. Pain in right hypochondrium. Evening fever; thirst; constipation; chilliness and rigors. One attack of vomiting; loss of flesh. Swelling over liver, later resembling a carbuncle. No fluctuation.	*Recovery.* Poultices followed by incision. Pus contained bile and liver-tissue. Probe passed four inches. Duration about five weeks.	
10	Mall, C. D.	Wiener Med. Presse, 1873, xiv. 636.	12	F.	——. Taken sick with severe chills followed by violent pains in liver. Six days later, febrile symptoms, frequent bilious vomiting; painful swelling in right hypochondrium, tenderness; stools sluggish; urine scanty and dark-colored. Whole body slightly icteric. Liver enlarged and prominent. On sixteenth day, signs of abscess.	*Recovery.* Abscess opened about five weeks (thirty-six days) from first symptom. Three weeks later, opening closed. Duration eight weeks.	

TABLE.—*Continued.*

No.	Reporter.	Reference.	Age.	Sex.	Cause and Symptoms.	Result, Course, Treatment,	Remarks.
11	Bernhard, A. (Koht's Clinic).	Jahr. f. Kind., N. F., 1886, xxv. 303–50.	13	M.	*Ascarides?* Taken acutely sick with symptoms of pleurisy; effusion; remittent fever. Aspiration withdrew grayish-green, feculent-smelling pus; subsequent resection. Pleural effusion serous; pus came from liver-abscess. Œdema of right face, eyelid, thorax, and arm. Death three days after operation.	*Death.* Autopsy: large liver-abscess toward diaphragm; duodenum contained a large number of round-worms. Duration six weeks.	
12	Scheuthauer (quoted by Bernhard).	Jahr. f. Kind., 1879, xiii. 63.	4	M.	*Ascarides.* Sick six weeks with slight fever, pain and cramps in bowels; one week later, left-sided pleurisy; four days later, diarrhœic stools containing ascarides; five weeks later, right-sided pleurisy and effusion.	*Death.* Autopsy: right-sided empyema. Two abscesses in liver; in one is an ascaris, and in ductus choledochus there are several; they are scarcely true abscesses. Duration nine weeks.	
13	Von Lebert (quoted by Bernhard from Gerhardt's Handbuch).	Jahr. f. Kind., 1886, xxv. 303–50.	15	F.	*Ascarides.* Taken sick with chill, fever, violent pain in right portion of belly, and diarrhœa. Liver enlarged and painful. Fourteen days later, cough; two days later, rejection of ascarides by vomiting and by stool. Eight days later, right-sided pneumothorax began to develop.	*Death.* Autopsy: right pneumothorax. Bile-ducts much dilated and containing ascarides; large abscess of liver which had broken through the diaphragm. Several abscesses communicate with bile-ducts, and two contain macerated ascarides, one especially soft and decomposed. Ascarides in intestines. Duration five weeks.	
14	Davaine.	Traité des Entozoaires, pp. 156–175 (quoted by Bernhard, *l. c.*).	. . .	M.	*Ascarides.* End of January, 1829, diarrhœa, vomiting, general weariness. March 18, belly tense, enlarged, sensitive to slightest pressure, especially over liver. Pneumonia.	*Death.* Autopsy: pneumonia. Thirty ascarides united in small balls in small intestine. Three pus-cavities in liver, one containing an ascaris. No	

						communication with bile-ducts demonstrated. Duration three months.	
15	Bluff.	Medicin. Annalen, 1885, Bd. I., Heft 3, S. 472 (quoted by Bernhard, *l. c.*).	15	F.	*Ascarides.* In July, 1834, intermittent fever, disappeared about October 18; about October 15, pain in epigastrium; ascarides found in stools. In evening, slight chills and consecutive fever. Toward December, swelling of belly, later of thighs and legs. Fluctuation at navel; lanced; four quarts of "liver-pus" obtained, the flow increased by stroking from liver towards navel.	*Recovery.* Might have been a sacculated peritoneal abscess (Bernhard). Duration six months.	
16	Renaud.	L'Union Méd., 1851, No. 37 (quoted by Bernhard, *l. c.*).	1⅓	. . .	*Traumatic.* Fell and struck on right hypochondrium. Tumor noted in six weeks. No jaundice and no digestive disturbance. Tumor in right hypochondrium, fluctuating and pulsating.	*Death.* Abscess opened by incision. Fistulæ formed and wound became gangrenous. Autopsy: abscess in upper anterior surface, and several small ones in lower and external third. Duration seventeen days.	
17	Löschner.	Jahr. f. Kind., 1860, S. 70 (quoted by Bernhard, *l. c.*).	11	M.	*Traumatic.* Struck with fist in right hypochondrium. Pain; febrile symptoms; cough. Fourth day, icterus; right-sided pleurisy. Sixth day, shivering and great heat. Eighth day, chill. In upper part of belly was a resisting, very painful spot, corresponding with the liver.	*Death.* Autopsy: abscess in upper half of right lobe. Right-sided fibrinopurulent pleurisy. Duration thirteen days.	
18	Baudelocque.	Schmidt's Jahr., 1834, iv. (quoted by Bernhard, *l. c.*).	11	M.	*Traumatic?* Said to have sustained a fall four weeks before. The last survivor of a tuberculous family. Had phthisical symptoms.	*Death.* Autopsy: liver somewhat enlarged. In right lobe were from twelve to fifteen pus-cavities. Bile-ducts normal. Phthisis. Duration six weeks.	

TABLE.—*Continued.*

No.	Reporter.	Reference.	Age.	Sex.	Cause and Symptoms.	Result, Course, Treatment.	Remarks.
19	Romberg.	Caspar's Wochenschrift, 1837, No. 18, S. 292 (quoted by Bernhard, *l. c.*).	5	F.	——. Icterus; fever; pain in right hypochondrium; thirst; constipation. Saffron color of urine.	*Death.* Autopsy: liver not enlarged; surface of right lobe contained a number of small foci of suppuration. Duration seven days.	
20	Wendroth.	Med. Zeitung, 1834, No. 34 (quoted by Bernhard, *l. c.*).	3	F.	——. Suffered from birth with a skin-eruption, on the disappearance of which a tumor the size of a hen's egg formed in right hypochondrium. No fluctuation. In ten days sudden chill, evening fever, sweats.	*Recovery.* Relations of tumor examined by the finger through opening,—undoubtedly liver. Tumor lanced. Duration four weeks.	
21	Dulles, C. W.	Phila. Med. Times, 1878–79, ix. 300.	12	M.	——. Diarrhœa two weeks; then constipation; patient gradually became yellow. Pain at edge of ribs. In about eleven days tumor; fluctuation.	*Recovery.* Aspiration; incision. Duration about six weeks.	
22	Bach, J. A.	Therap. Gaz., January 15, 1887.	9	M.	*Pyæmic.* Badly bruised on left hip, followed by abscess. On tenth day great enlargement of liver; a few days later two tumors size of goose-eggs.	*Recovery.* Poultice, aspiration, incision. In three days, abscess of left lobe of liver treated in the same way.	
23	J. Wickham Legg.	St. Barthol. Hosp. Rep., 1875, xi. 85.	5	F.	——. Had had abscess in groin eighteen months before, which broke and healed. Admitted June 30, 1874, for abscess between the umbilicus and the epigastrium; opened; wound healed and child dismissed. Re-entered September 21, worse.	*Death.* Autopsy: numerous abscesses in abdominal cavity. Abscess in posterior part of left lobe of liver. Numerous abscesses elsewhere. Scar on upper surface of right lobe, possibly from healed abscess where the latter had been opened. Duration probably some months.	

24	Murchison.	Clin. Lec. Dis. of Liver, 1877, p. 171.	15	M.	*Pyæmic.* Symptoms secondary to rupture of vermiform appendix. In seventeen days the liver was found to be enlarged and tender. No rigors, but temperature subject to great and sudden variations; sweats.	*Death.* Autopsy: healed inflammation of appendix. Both lobes of liver studded with numerous small circumscribed abscesses. Glands in fissure of liver enlarged and suppurating. Other organs healthy. Duration about ten weeks.	
25	Sinnhold.	Jahrbuch f. Kind., 1879, xiii. 288.	5½	F.	*Ascarides.* Bilious vomiting, pain in belly, passage of round-worms by mouth and anus. Liver enlarged, tender; thirst, with frequent chills, followed by fever and sweat.	*Death* on twentieth day. Autopsy: liver enlarged,—seven inches long, eleven inches broad. Several abscesses in liver.	No history of traumatism. Endocarditis developed late in disease.
26	Bernhard, A.	Jahrbuch f. Kind., N. F., 1886, xxv. 303–350.	10	M.	Secondary to *pylephlebitis* from perityphlitis. October 27, 1884, symptoms of perityphlitis; twenty-two days later, prominence in right side of belly first seen; fever pyæmic, intermittent; chills.	*Death* on twenty-fifth day from beginning of disease. Autopsy: fibrinous and purulent peritonitis, secondary to pylephlebitis. Series of walnut-sized abscesses on upper surface of right and lower surface of left lobe.	
27	Bernhard, A.	Jahrbuch f. Kind., N., F., 1886, xxv. 303–350.	12	M.	Secondary to *pylephlebitis* from typhoid fever. On twenty-seventh day of typhoid fever, a chill; two days later, violent pain in region of liver. Elastic tumor at lower edge of ribs, right side. No fluctuation. Fever intermittent. Chill not repeated.	*Death* on thirty-fifth day of disease. Autopsy: healed typhoid ulcers in bowel, and pylephlebitic abscesses proceeding from suppurating glands of ileo-cæcal cord.	
28	Burder.	Lancet, 1874, ii. 552.	9	M.	Secondary to *pylephlebitis.* Typhoid symptoms, with chills and jaundice.	*Death* on seventeenth day. Autopsy: ileum and cæcum full of ulcers,—superficial, with no ragged edges in Peyer's patches. Liver a mass of small abscesses.	Burder does not think the patient had typhoid fever.

TABLE.—*Continued.*

No.	Reporter.	Reference.	Age.	Sex.	Cause and Symptoms.	Result, Course, Treatment.	Remarks.
29	Löschner.	Jahrbuch f. Kind., 1859, S. 140.	10	F.	Secondary to *pylephlebitis.* Began with general jaundice. After seven weeks, could not leave bed. Frequent epistaxis. Much emaciation. Liver enlarged,—double normal size. Small, painful elevation on anterior surface. Stools contained bile and blood.	*Death* in six weeks. Autopsy: large liver full of minute abscesses.	Löschner believes pylephlebitis was secondary to stasis in portal circulation, arising from obstruction of bile-ducts. But, Bernhard asks, why should stasis in this case give rise to suppuration? Patient in hospital under observation only five days.
30	Sheets, L. D.	Cincin. Med. Observer, 1857, ii. 9–11.	12	M.	*Traumatic.* Fell upon a sharp corner of a chair, in August, 1855, and probably fractured a rib. Pain was severe, but subsided in a few days. In October, was seized with chills, which were soon broken up, but health was not restored. In March following, a prominence was discovered in the right side and lower part of chest; later, decided fulness. Liver enlarged, ribs bulging; feet slightly œdematous, bowels costive, tongue furred, appetite poor.	*Recovery.* Incision between ninth and tenth ribs April 10. Abdominal fluid, blood, and pus evacuated. On September 14, a piece of broken rib was removed by the patient, and a few weeks later the discharge ceased and the wound closed.	A fracture of the rib was unsuspected at the time of the accident, but the author thinks the abscess of the liver was secondary to the fractured rib, and was produced by irritation. Duration uncertain, probably about eleven months.
31	Drechsler.	St. Louis Med. and Surg. Jour., 1869, N. S., vi. 39–41.	13	M.	*Traumatic.* Was lying upon his belly on a sled, when another boy fell on him. Since then pain in right side. Subsequently, vomiting, chill, high fever, dry skin, acute pain in right hepatic region. Physical signs: dulness on percussion, and a small hard swelling about the size of a hen's egg.	*Death.* When apparently convalescent, February 13, he coughed up about a pint of bloody pus, apparently from the right lung.	The case was supposed to be one of acute congestion of the liver. There was no autopsy.
32	Dunn, T. D.	Univ. Med. Mag., November, 1889.	14	F.	Believed to be *secondary to a pelvic peritonitis.* Chill, high fever, rapid pulse, painful and shallow respiration, tenderness over liver. Later, rigors and sweats, increased hepatic swelling and tenderness; respiration shallow, quiet, and painful. No jaundice; no	*Recovery.* Aspiration, followed by improvement in symptoms. Night-sweats continued, but with no rigors. Emaciation marked. Subsequent re-	Microscopical examination of the pus disclosed the presence of blood, pus-cells, shreds of tissue (organ not mentioned), but no bile or biliary

					bile in urine; alvine discharges natural. Bulging over liver.	filling of abscess and aspiration, and then abscess opened spontaneously through puncture. Cavity washed out with carbolized water.	pigment. Duration of case, from symptoms believed to be the initial ones of abscess of liver, about forty days. Patient has since borne two children.
33	Berton.	Traité prat. des Maladies des Enfants, Paris, 1842, p. 670 (case quoted from Gaz. Méd., March 16, 1834).	11	M.	Had presented all the symptoms of pulmonary phthisis.	*Death.* Autopsy: double pleuro-pneumonia. Bronchial glands hypertrophied but non-tubercular. Liver a little larger than normal, and containing fifteen purulent foci. No jaundice.	Case referred to by Berton as one of "tubercle of the liver."
34	Brown.	Trans. Medico-Chirurg. Soc. Edinburgh, 1861, i. 665.	1	F.	*Ascarides?* Subject to diarrhœa for two months, passed worms by bowel, and had bloody stools occasionally. Liver found enlarged when abdomen was examined day before death. Much emaciation.	*Death.* Autopsy: deep ulceration of the size of a dollar in both lobes of the liver. In right lobe immediately under margin of ribs was an abscess containing about three ounces of a bloody matter, rather thin in consistence. Stomach, bowels, and other viscera healthy.	

CONTRACTIONS OF THE LIVER:

CIRRHOSIS (ATROPHIC AND HYPERTROPHIC), ACUTE YELLOW ATROPHY, AND ASCITES.

By MARCUS P. HATFIELD, M.D.

CIRRHOSIS OF THE LIVER.

Synonymes.—Cirrhosis hepatis, Chronic interstitial hepatitis, Hob-nailed liver, Drunkard's liver, Gin liver; French, Cirrhose du foie; German, Granulirte Leber.

Definition.—Sclerous inflammation of the liver, located either in its fibrous tissue, capillaries, lymphatics, or bile-ducts, separately or combined.

Varieties.—The simplest division of hepatic cirrhosis is that proposed by George Monroe Smith,—viz.: (1) *Obstructive*, which may be subdivided into (*a*) biliary, or that arising from impeded bile-flow; (*b*) static, or that originating in some interference with the flow of blood from the liver; (*c*) cyanotic. (2) *Irritative*, or that due to the presence of some toxic substance in the blood carried to the liver by the portal vein or the hepatic artery. Under this head may be grouped the cirrhoses which follow alcoholic excess, malaria, syphilis, rickets, scarlatina, etc.

Hepatic cirrhosis is, however, more frequently divided into *atrophic* and *hypertrophic*. The former is so named from the contraction of connective tissue which follows as a secondary result of a previous inflammation and proliferation of the capsule of Glisson or other connective tissue of the liver. Hypertrophic cirrhosis is the biliary cirrhosis of G. M. Smith's subdivision, and is so named on account of an initial stage of increased size of the liver.

According to Hayem, there is a third variety of cirrhosis, originating in the lymphatics, also hypertrophic in form.

Salomon describes a fourth form of cirrhosis, which begins in the arterial system, producing a general arterio-sclerosis, of which interstitial nephritis is one of the more common complications. This form is not common with children.

Carpentier asserts that there is another form of hepatic cirrhosis, characterized by fatty degeneration of the liver parenchyma; but his views seem as faulty as the earlier views of Laennec, who first described cirrhosis as a special disease of the liver, deriving the name from *cirrhus*, "red," on account of the predominance of this tint in the granulated liver, as it was frequently called at that time. These granulations were by many considered analogous to tubercles, and were known as cirrhoses. Next Andral taught that there were two substances in the liver, a red (vascular) and a yellow (glandular), and that in cirrhosis the red substance atrophies, while the yellow substance hypertrophies. Becquerel (1840), Gubler, Kiernan, Hallmann, Charcot, Dujardin-Beaumetz, and others have attentively studied the subject, until it is now clearly understood that cirrhotic inflammation of the liver may originate either in its blood-vessels, in its lymphatics, or in the bile-ducts, and may remain confined to any one of these tissues, or involve them all conjointly; but it will be found always that obstructive cirrhosis is at first monolobular,—that is, the connective tissue grows irregularly, its hypertrophy being confined to certain lobules only. Finally, it may become impossible to differentiate monolobular from multilobular cirrhosis, and in the later stages hypertrophic may closely resemble atrophic cirrhosis.

Frequency.—It was formerly taught that hepatic cirrhosis was one of the rarest of the diseases of childhood. Dr. West says that of seventy thousand cases of children's diseases known to him, but four were cirrhosis of the liver. Birch-Hirschfeld says it is extraordinarily rare, Thierfelder calls it "absolutely rare," and Henoch asserts that it is never fully developed in children. Neureutter puts its frequency at one-tenth of one per cent. of the children brought to him, and Steiner's figures are about the same. Nevertheless, Dr. Palmer Howard has succeeded in collecting more or less complete accounts of sixty-three cases, to which the writer can add ninety-three reported during the past fifty years, making a total of one hundred and fifty-six cases, so that he fully agrees with Eustace Smith in the statement that there is every reason to believe that hepatic cirrhosis is less uncommon with children than is generally thought.

Age.—The largest proportion of recorded cases occurred in children between eight and fifteen years old, the majority of cases of alcoholic cirrhosis, naturally, being found in the elder children. Gibbons reports a case of biliary cirrhosis in a child of eleven months, and the writer[1] found it in a child dying on the twelfth day.

Varieties.—Their relative frequency is probably about that given by Lancereaux,—viz., of fifty non-syphilitic cases the cirrhosis was atrophic in nineteen, hypertrophic in thirteen, and the liver was of normal size in six; of the remaining cases (twelve) no data are given. Congenital cirrhosis is invariably syphilitic (Birch-Hirschfeld).

Fifteen per cent. of Dr. Palmer Howard's cases were in children known to be addicted to the use of spirits, in eleven per cent. there was a clear history of syphilis, eight per cent. were tuberculous, and the remainder were of unknown etiology.

---

[1] American Pediatric Society, 1889.

Sex.—Dr. Howard's cases seem to show that it is twice as frequent with male as with female children; Birch-Hirschfeld's, exactly the contrary.

Etiology.—According to Dr. Lancereaux (Hôpital de Pitié, Paris), there are but three well-established causes of primary cirrhosis of the liver, —viz., (*a*) alcoholic, (*b*) malarial, (*c*) syphilitic. "All other forms of cirrhosis are secondary, arising from other and primary disorders, such as hepatic hyperæmia, due to heart-disease, obstructions to the bile-flow, and cancerous or other infiltrations, all of which show elsewhere their characteristic pathological changes."

In regard to *alcoholic* cirrhosis, its existence in children has been doubted, but there seems to be the best of evidence as to its occurrence, although, from the nature of the case, alcoholic cirrhosis is not often susceptible of direct proof in young children. Frerichs reports that of the thirty-six cases of cirrhosis in children observed by him twelve were known to have been brandy-drinkers. Out of Bamberger's thirty-four cases ten followed brandy-drinking, and ten of Howard's sixty-one cases were traceable to alcohol. In short, about one case in four (thirty-two out of one hundred and thirty-one) of all those reported by the above authors was directly due to alcohol. Nothing, says Strauss, is more natural than the localization of alcoholic cirrhosis, for the alcohol comes directly to the liver by the finer branches of the portal vein and exerts first of all its baneful influence on the points where its contact is most intimate.

Ptomaine Cirrhosis.—Peter and Roger, of Paris, have found that the ptomaines and other alkaloid products of retrograde metamorphosis are destroyed in their passage through the liver, since the portal blood contains about twice as much of these substances as the blood coming away from the liver. Moreover, these products when administered subcutaneously are much more virulent than when injected into the portal vein. All these facts seem to prove that the liver acts as a crematory for the destruction of the leucomaines and ptomaines formed within or introduced into the body. Failure to accomplish this constitutes one form of hepatic incompetence, and, in all probability, at last a variety of hepatic cirrhosis, especially in cases predisposed thereto. Howard's cases seem to suggest that such predisposition is often inherited, occurring in several members of the same family, with whom a rich, stimulating diet acts as injuriously as alcohol on a liver predisposed to interstitial changes.

Dietetic and Zymotic.—Overfeeding acts primarily as a stimulant to hepatic tissue, and theoretically brings as an after-result cirrhotic changes analogous to those of interstitial nephritis, which is frequently excited by a diet too largely nitrogenous. As a rule, these changes are not as frequently met with in the child as in the adult, but the *modus operandi* is identical, except that in the child the overtaxed liver is apt for a while to relieve itself by critical fluxes, or so-called bilious attacks, but finally chronic hepatic incompetence is established, and true cirrhotic changes begin. Closely allied to these are the cirrhotic changes produced in the liver by the decomposition-products of *phthisis*. Tubercles frequently are deposited in the liver, impairing its function, but aside from these we meet in phthisis with cirrhotic changes determined, as the writer believes, by the toxic action of the ptomaines generated by the decomposition of disorganized tissues. This is well known to follow scarlatina occasionally,—*e.g.*, Klein reports eight cases of interstitial hepatitis following scarlet fever; and similar lesions are not infrequent in other infectious diseases which have long been known to originate chronic inflammatory changes in the various excretory organs (Botkin).

The action of these zymotic poisons upon the liver is in all probability analogous to that of alcohol, or to that of tea, which if taken to excess, as by tea-tasters and Siberian exiles, not infrequently determines a true cirrhosis of the liver.

Rickets.—It seems fair to conclude that any cause which persistently obstructs the normal action of the liver may lead eventually to cirrhotic changes in that organ, which may be induced, some think, even by chronic gastro-intestinal catarrh. This is Dr. Hogben's[1] explanation of that form of hepatic cirrhosis which he believes to be due to rickets. It is certainly not infrequent in rachitic children, and in its general appearance and microscopically resembles ordinary hypertrophic cirrhosis. The changes observed in the bile-ducts and canaliculi led Hogben to believe that their lesions originate in a chronic obstruction to the flow of the bile, due in all probability to the chronic gastro-intestinal catarrh so frequently associated with rickets.

Similarly, either from the action of a specific poison or from a general hepatic congestion, we find produced the typical forms of cirrhosis associated with syphilis and malaria which are discussed later under their proper headings.

Pathology and Pathological Anatomy.—Engorgement of the hepatic veins from any cause leads eventually, says Eustace Smith, to atrophy of the hepatic cells. These atrophied cells are stained deeply with bile, and at the circumference of the lobule the cells are often filled with oil. Finally a fibroid tissue supplies their place and by its contractions a condition akin to cirrhosis is produced.[2] This is perhaps Carpentier's cirrhosis, rather than Charcot's, which begins as a periphlebitis, whose initial lesions are those of chronic inflammations of the branches of the portal vein, resulting in a proliferation of embryonic cells which subsequently are transformed into an excessive amount of fibrous tissue. A more careful study of these changes seems to show good reason for the following convenient divisions.

(*a*) *Alcoholic Cirrhosis*.—Strauss's experiments in regard to the artificial production of cirrhosis (Society of Biology) prove that alcoholic cirrhosis may be induced in rabbits (dogs were too sensitive) by pouring down the œsophagus one-half ounce of absolute alcohol and methyl alcohol diluted with three parts of water. The first effect of this injection in the majority of these animals was to cause them to fall as if paralyzed, and to lie for several hours in coma. If alcohol was given for several months and the rabbits were then killed, the usual lesions of chronic alcoholism were found, —viz., thickening of the gastric mucous membrane, ecchymotic petechiæ, etc. The liver did not present any marked alteration to the naked eye, but the microscope clearly revealed, in the livers of those animals which had been kept intoxicated for three or four months, that the acini were surrounded by a reddish-gray line, and the ultimate perilobular portal spaces were found infiltrated with embryonic cells.

---

[1] Birmingham Medical Reporter, August, 1888.

[2] Eustace Smith, p. 722.

Hares that were subjected to alcoholic intoxication for seven or eight months showed the hepatic lobules completely surrounded by a crown of connective-tissue cells presenting typical forms of annular, perilobular, and monolobular cirrhosis.

(*b*) *Rachitic Cirrhosis.*—Hogben's observations made on the livers of rachitic children, after taking pains to exclude all cases in which there was a suspicion of tuberculosis, syphilis, or alcoholism, revealed, as a rule, the liver tough, solid, and heavier than would be usually estimated from its appearance. The surface was smooth and of a color varying from that of deep congestion to the red mottling of fatty infiltration. There was in all cases an increase of the fibrous connective tissue, occasionally associated with fatty infiltration of the hepatic cells. The fibrous growth was most marked as interlobular connective tissue, surrounding and isolating the individual lobules. In the immediate neighborhood of the interstitial growth and at the periphery of the lobules there was at times a small cell-infiltration, derived apparently from the interlobular connective tissue, which encroached upon the hepatic cells at the margin of the lobules. Occasionally there was also a very marked thickening of the coats of the bile-ducts, and there seemed also to be a multiplication of the biliary canaliculi.

(*c*) *Atrophic Cirrhosis.*—A cross-section shows a yellowish-red liver-substance traversed by a fibrous net-work, which net-work holds within it the branches of the portal vein and extends into the interlobular spaces, where it forms meshes of various sizes, enclosing several lobules within them. The later contraction of this fibrous net-work flattens and at last atrophies the liver-cells embraced within its meshes. For the same reason there is diminished circulation in the hepatic portal system, since the lumen of these vessels is diminished by their lessened size. The hepatic venous system proper—intralobular, sublobular, and the hepatic trunks—does not participate in this form of cirrhosis. In other words, in atrophic cirrhosis the hyperplasia of the connective-tissue framework compresses the hepatic cells and presses upon their venous capillaries. This morbid process begins in the finer ramifications of the portal vein, the interstitial inflammation being located chiefly in the cellular tissue surrounding these veins,—*i.e.*, in Kiernan's interlobular spaces. The smaller bile-ducts are but little affected by these changes, since the blood-supply by which the liver is nourished and the bile is formed is preserved by vessels developed in the neoplasm (Starr). Subsequent contraction of this hyperplastic tissue is the cause of the dense structure and nodulated surface of the liver found in hobnailed liver in the post-mortem examination of these cases. The edges of the liver are thin, while the capsule is thickened.

(*d*) *Hypertrophic Cirrhosis.*—In the hypertrophic form of cirrhosis the liver is enlarged, sometimes to twice its normal size. Its surface is smooth, its edge thin, and the cross-section is orange or greenish yellow. The fibrous proliferation in these cases begins around the intralobular branches of a bile-duct, enveloping and *isolating separate lobules.* The fibrous growth therefrom follows each ramification of the bile-duct, is more diffused than that met with in the atrophic form of cirrhosis, and is of varying thickness and density. The portal circulation is therefore not necessarily obstructed, while the bile-ducts are not only obstructed but also dilated and show an increase in the thickness of their epithelial lining. Such persons become rapidly and progressively jaundiced and usually die of profound or malignant icterus. This is Charcot's biliary cirrhosis, the name originally indicating that cirrhosis arises from a blocking up of the bile-ducts. Latterly the name has lost in a measure its first meaning, and it is now used to denote increased formation of small bile-ducts from any cause whatever.

Pathological Complications.—The most frequent of these is *splenic enlargement*, which may be found in both atropic and hypertrophic cirrhosis, due, as Dujardin-Beaumetz suggests, to an effort made to relieve the stasis in the congested portal mesenteric veins.

The *kidneys* may also participate in the general parenchymatous degeneration, and in the profound icterus of the later stages of hypertrophic cirrhosis they contain bilirubin infarcts. The urine in such cases contains not only biliary coloring-matters but the bile-acids as well, since there is frequently an excess of uric acid present in this secretion, due, as Granville thinks, to the primary failure of the liver to furnish the proper amount of bile to co-operate with the pancreatic juice. This produces duodenal indigestion, according to the previously mentioned writer, because the food-elements are only emulsified, and not saponified as they ought to be, and the result is *lithæmia*, which may be associated with hæmoglobinuria or cholæmia.

During the past year considerable attention has been given to the study of the urobilin which appears in the urine in cirrhosis. Some suppose that urobilin is formed from biliary coloring-matters, and that under certain circumstances it is deposited in the tissues and reappears in the urine; others, that it is only an exaggeration of the pigment that gives urine its red tint and varying according to the quantity of urobilin present, which may or may not be associated with biliary pigments. Urobilinuria also occurs in cancer, in lead-poisoning, in alcoholic poisoning, and in rheumatism, gout, pneumonia, angina, and intermittent fever. Hence Hayem considers urobilinuria a proof of hepatic incompetency, due to a languid liver manufacturing urobilin instead of normal bile-pigments. Urobilin is then taken up by the urine, and its persistent appearance therein is a matter of considerable importance in prognosis. It should also be remembered that albuminuria is necessarily associated with continued venous stasis of the liver (Hayem).

Symptomatology.—(*a*) *Alcoholic.*—The symptoms arising from the use of alcoholic liquors in the child differ but little from those characterizing their abuse in the adult. Hence we find, as might be expected, disturbances of digestion, gastric catarrh, etc., alternating with periods of comparative health, attended in some cases with an excessive appetite. Murchison reports a case in which the child suffered from the morning vomiting of a confirmed toper and within a month developed ascites.

The quantity of spirits used daily by some of these children is remarkable, as, for instance, the case reported by Wilkes of an eight-year-old girl who drank daily one-half pint of brandy. The literature of the subject is very imperfect, and there is a remarkable absence of the nervous symptoms which are observed in the adult in similar cases, and which might naturally have been looked for in the child, who dies, as a rule, apparently from ascites and cholæmia, rather than from the delirium tremens of the adult.

(*b*) *Atrophic cirrhosis,* in all its varieties, is characterized in its earlier stages by the usual symptoms of hepatic incompetence,—viz., a metallic or coppery taste in the mouth, an unnatural craving for food, often appearing immediately after eating and varying from slight discomfort to actual gnawing distress allayed only by more food. Or the dyspeptic symptoms may take the form of anorexia and distaste for food, thirst, and marked irritability. There may also be weariness and weakness of the lower limbs, which are unable to perform their usual duties except under protest and subsequent aching, as if they had been forced to do some difficult task. Another and a more unusual symptom is that of a distressing morning sickness, not unlike that of pregnancy, except that the vomited matter is sour or bitter, according to the relative proportion of gastric juice and bile it may happen to contain, together with a copious supply of mucus. Sharp attacks of temporary diarrhœa are apt to supervene, and general impairment of nutrition is apparent, for in atrophic cirrhosis circulation is chiefly interfered with. Hence in this form of cirrhosis the earlier symptoms are those of flatulent indigestion, with its accompanying discomforts. The child is restless at night, and peevish and irritable during the day. Dark circles appear beneath the eyes; the muscles are flabby; the urine may be loaded with urates and give the usual brick-dust deposit, and is often very acid. In other words, we have *uric-acid lithæmia,* or failure of the liver to transform albuminoids into urea. It does not particularly concern us at what stage in the digestive process this failure takes place. It is sufficient for clinical purposes to know that such failure is very frequent with children, and produces the symptoms given above and long ago described by Murchison under the name of lithæmia.

Other, and no less important, symptoms of hepatic incompetence are those of headache, fever, and chill, often wrongly ascribed to malaria. Malaria, if it exists in these cases, is a malaria generated within the child's organism, and is in all probability due to leucomaine or kindred intoxication. The leucomaines are in general virulent poisons, producing death when hypodermically injected into the lower animals. Gauthier's experiments prove that auto-infection with these leucomaines is not only possible but inevitable whenever they accumulate in the system to such an extent that their destruction is not accomplished by the usual emunctories. Chief among these agents his experiments place the liver. The failure of this to perform its duty, either in whole or in part, produces much of the continued malaise met with in children, wrongly named and falsely treated as "dumb ague."

These prodromal symptoms are usually overlooked, or misinterpreted, until ascites attracts the attention of the parent, or of the physician, to whom such children are not brought, as a rule, until the enlarged abdominal veins or dropsical effusions clearly point to the source of the child's continued ill health.

In atrophic cirrhosis there is often no real jaundice, though the skin feels rough and dry and assumes an earthen tint. The ascites (for which see page 511) is variable in amount. The feet and limbs may also become œdematous from the pressure of the fluid contained in the abdomen.

The later stages of fatal cases of hepatic cirrhosis are marked by symptoms due either to ascites or to progressive incompetence of the liver, such as increasing weakness, emaciation, and leucomaine-poisoning. The tongue is rough and furred, and fever, at first and for a long time absent in these cases, at length appears, and is of a clearly-marked remittent type and often mistaken for fatal intermittent. More frequently death results from progressive starvation, the dyspeptic symptoms becoming more aggravated as the disease advances. Vomiting is now troublesome, and there is a constant sense of weight in the stomach. Abdominal pains are frequent. The tongue is constantly furred and the appetite completely lost. Thirst is abnormal. The child wastes, and its complexion grows dingier than ever. Hemorrhoids and consequent pruritus are not infrequent. The child grows weaker, until at last it dies, either from general dropsy (spanæmia) and diarrhœa, or from exhaustion without the appearance of any new symptoms. In other cases death may result from internal hemorrhage, pleurisy, or pneumonia.

The initial symptoms of the *hypertrophic variety of cirrhosis* are about the same as those met with in the atrophic form,—viz., gastric dyspepsia, pallor, and wasting. Later other symptoms develop, due to interference with the proper circulation of the bile; hence, while we find jaundice rarely present in atrophic cirrhosis, it is a well-marked and early symptom in the hypertrophic form. The skin, conjunctivæ, and urine are those characteristic of obstructive icterus, and the passages from the bowels present the usual clayey appearance of catarrhal jaundice. Pain over the liver is tolerably constant. The bowels are exceedingly variable, now constipated and again relaxed. With the progress of the disease the icterus deepens, and the liver may for a period rapidly enlarge, with increase of pain in the side, fever, and fretfulness. Again, there may be temporary amelioration, but the course of the disease is steadily towards death, although at times the general condition of the child is perplexing,—on some days apparently nearly well, lively and playful, and on others too cross and irritable to be endured, but easily tiring in either condition.

The later stages of hypertrophic cirrhosis are frequently attended with hemorrhage from the gastro-intestinal mucous membrane, the blood being vomited, or passed with the stools, which in consequence are usually black and tarry, though occasionally bright red if the hemorrhage is profuse. The latter condition could hardly escape the attention of the physician, but small quantities of changed blood in the stools might not be noticed unless they are placed in water, which becomes red if blood is present, but only greenish or brown from altered bile-pigments, affording an easy method of diagnosis in doubtful cases.

Bleeding may also take place from the gums and nose, or petechiæ may show here and there upon the body. The case may even terminate fatally from exhaustion consequent upon hemorrhage. According to Cyr, this is frequent in the later stages of both forms of cirrhosis (one in thirty-eight of atrophic and one in forty of hypertrophic cases), but, as a rule, a case of hypertrophic cirrhosis dies with the symptoms of malignant jaundice, or cholæmia. This is characterized by curious alternations in the frequency of the pulse, which is that of septic poisoning, as proved by the dry brown tongue, sordes on the teeth, etc. The child is heavy and drowsy, refuses food, and wishes only to be left undisturbed. Ecchymotic spots, or bleeding from the gums, may complicate the case, or with these there may be hæmatemesis. Drowsiness passes into stupor, the child lying insensible, grinding its teeth constantly, until death occurs, either by convulsions or by deepening unconsciousness, all without fever, as a rule.

Physical examination in the earlier stages of atrophic cirrhosis shows slight enlargement of the liver and spleen. Later the liver shrinks and cannot be easily felt, but the spleen continues to increase in size. In hypertrophic cirrhosis the enlargement of the liver can be more easily detected.

According to Eustace Smith, both forms of cirrhosis may be conjoined in the same child, for their lesions affect different structures in the liver. Such cases would present a combination of symptoms very puzzling to the diagnostician unacquainted with this fact, for in such children we might expect to find enlargement of the liver, jaundice, and hemorrhage, associated with ascites, dilatation of the abdominal veins, and splenic enlargement.

Splenic enlargement is generally found in both the atrophic and the hypertrophic forms of cirrhosis, in the former of which it may be difficult of detection if complicated with any considerable amount of ascites. Even then it can usually be detected by resorting to the manœuvre of putting the child upon its hands and knees, which brings the enlarged organ well forward by its own weight and places it easily within reach of the physician's fingers.

Intercurrent Diseases.—The more frequent of these are pleurisy, pneumonia, peritonitis, and ascites, elsewhere described.

Interstitial changes in the lungs and kidneys similar to those in the liver are sometimes present, but, as a rule, the kidneys maintain their functions well to the last.

Differentiation.—The differential diagnosis of the earlier stages of any form of cirrhosis is a task no easier in the child than in the adult. We may, however, fear its onset whenever there is an inexplicable persistence of hepatic incompetence. This does not necessitate clay-colored stools, for hepatic incompetence may exist with normal-colored fæces, and, *per contra,* the liver may be efficiently performing its work, and yet intestinal catarrh, or a milk diet, may produce the light stools which are thought to require a mercurial powder. Again, hepatic incompetence does not require that the liver should be enlarged, though a chronically congested liver becomes thereby eventually more or less incompetent. On the other hand, it is well to remember Eustace Smith's hint, that "the liver is apt to vary in size from natural causes in young children, some having exceptionally short chests and causing the liver without enlargement to be displaced a finger's breadth or so below the ribs. Again, empyema, emphysema, or pericardial effusion may do the same; hence in rickety children both liver and spleen may be felt below their normal position, or, *vice versa,* an enlarged liver may be pushed upward by fluid in the abdomen, or drawn upward by the contraction of the lung."

The same author well says that "many symptoms attributed to a torpid liver and treated with gray powder are really due to a disordered state of the stomach arising from an improper dietary." Nevertheless, while gastric catarrh may be mistaken for hepatic incompetence, the error is more frequent in the other direction, for sick headache, anorexia, and gastric catarrh and diarrhœa more often originate from leucomaine-poisoning than *vice versa.* In its later stages the diagnosis of atrophic cirrhosis ought to be no more difficult in the child than in the adult, for ascites, an enlarged spleen, and dry, earthy skin, without fever, render a diagnosis of atrophic cirrhosis reasonably certain, especially if this condition has been preceded by failing health for some time previous. If to these is added hemorrhage from the stomach or bowels, with a normal temperature, it will strongly confirm our diagnosis. Febrile complications may obscure the diagnosis, but it should be remembered that such febrile exacerbations are common to all chronic diseases of children, and in doubtful cases the diagnosis should be reserved until the febrile attack subsides.

Hypertrophic cirrhosis may be recognized by its progressive jaundice, enlarged and painful liver, wasting, and persistent dyspepsia. Ascites, enlarged abdominal veins, and hemorrhoids are generally absent. Such cases are apt to terminate with the symptoms of malignant jaundice, which in many cases may be readily mistaken for those of acute yellow atrophy, especially if the liver is but slightly enlarged.

Amyloid degeneration may be excluded if its usual causes—phthisis, chronic suppuration, etc.—have been absent from the history of the case.

Urobilinuria (see page 493) may be of value as indicating fatty degeneration of the liver-cells. Urobilin is easily demonstrated, as its detection requires only the addition of the suspected urine to colorless nitric acid. The urine is added as in the nitric-acid test for albumen, and becomes deep brown, growing lighter as it recedes from the acid, if urobilin is present.

Prognosis.—In general the prognosis is bad. Marked wasting and an earthy tint of the skin are of unfavorable import, but even a considerable degree of ascites is not necessarily fatal if otherwise the general health is not seriously impaired.

In alcoholic cirrhosis, if detected early, the prognosis is greatly improved by the early and complete abandonment of all forms of alcohol. A gloomy prognosis must be given in all cases where there is progressive jaundice, especially if accompanied with febrile symptoms, drowsiness, or nervous manifestations. Urobilinuria is not a favorable symptom.

Recent discussions of cirrhosis in the French medical journals give better hope of recovery than was formerly believed possible. Troisier reports apparent cures, and believes that there is a stage in cirrhosis—especially alcoholic—in which the lesions have not yet proceeded to actual destruction of the liver-cells, and hence are curable. His results and those attained by others in the treatment of malarial cirrhosis seem to render this view probable, although Birch-Hirschfeld declares that the prognosis of hepatic cirrhosis is "entirely unfavorable, such cases proceeding more rapidly to a fatal termination with children than with the adult." Cyr regards it as the most dangerous form of hepatic disease.

Hemorrhage in either variety of cirrhosis is, as a rule, good proof of an early fatal termination. The same holds true in regard to the appearance of pernicious icterus. Delirium and coma are most discouraging complications and portend an early demise.

In the main, it may therefore be said that treatment is discouraging but not hopeless, and is the more favorable the earlier it can be commenced.

Treatment.—*Prophylactic.*—First and foremost, wherever cirrhosis is even suspected, must be placed the immediate abandonment of alcohol, if it has been used in any form, with prompt attention to the child's digestion. This may be aided by alkalies or tonics and by keeping the bowels open with a mild aperient. Many cases need also quinine and iron unless the tongue is furred and the child feverish.

Hepatic incompetence is an ailment never to be disregarded in children. It may never proceed to actual cirrhosis, but the possibility of such termination should always be borne in mind; the more so since the diagnosis of cirrhosis in its earlier stages, except in the alcoholic and malarial varieties, is a very difficult task. Attention to the matter of diet is of prime importance in these doubtful cases, for it should be remembered that excess of albuminous and stimulating foods produces engorgement of the hepatic veins, which in turn leads to engorgement of the liver-cells in their immediate neighborhood. This engorgement, according to Eustace Smith, leads eventually to a replacement of the liver-cells by fibroid tissue, which by its contraction produces a condition of affairs analogous to cirrhosis, if not true interstitial hepatitis. Hence the very great importance of such diet as shall not overtax the liver in the beginning of such cases. Starchy foods, bread-and-milk, fruits, broths, and broiled fish are articles which require the least assistance from the liver for their digestion, and are clearly indicated in the early stages of incompetence, which may often be thus relieved without the use of drugs. When, as frequently happens in these cases, there is a copious deposit of urates or uric acid in the urine, compound spirit of lavender or small doses of salicylic acid will be found helpful. The latter, combined with pepsin (one to two), will often be found especially useful where there is deficient secretion of bile and consequent intestinal fermentation; although pepsin, as a rule, does not give as good results in this class of cases as in other forms of dyspepsia, possibly because in intestinal dyspepsia we have decomposition-products formed from the malassimilation of peptones and parapeptones, and the use of pepsin simply increases these and their resulting toxic compounds.

Sick headache and migraine may be relieved by the use of a pill of ox-gall and oil of wintergreen (gr. i to gtt. i), aided by antipyrin during the intervals of pain. The latter remedy is also valuable in many of the so-called malarial (toxæmic) fevers of childhood, where we have regular intermissions and exacerbations, the fever in these cases often running for a few hours as high as in the initial stages of pneumonia or scarlet fever. These cases may be treated almost indefinitely by quinine and the other antiperiodics without relief, but are promptly cut short by a brisk mercurial purge and antipyrin in sufficient doses to keep the temperature down to normal, the drug in these and similar cases acting probably, in some way not yet explained, by assisting in the elimination of the leucomaines.

Where increased secretion of bile is clearly indicated, podophyllin, corrosive sublimate, or benzoate of ammonium or sodium will act most satisfactorily,—calomel assisting in the expulsion of the bile already formed, rather than increasing its amount. Complicating gastric catarrh and intestinal fermentation are relieved by the free exhibition of alkalies and laxatives, such as phosphate of sodium, senna, or calomel, preference being given to calomel, on account of its antifermentative properties.

Specific medication.—Troisier[1] reports cures of hypertrophic cirrhosis

---

[1] Annual of the Universal Medical Sciences, 1888, p. 339.

(in the adult) by means of full doses of potassium iodide with strychnine. Schreph claims similar results with an absolute milk diet and small doses of calomel, after Carlsbad salts and the other usual remedies had failed. Tincture of the chloride of iron with strychnine is recommended by Dr. W. H. Thompson. Others speak highly of the use of the iodides and corrosive sublimate. Cyr often employs cold compresses, with leeches about the anus in acute cases. Internally he administers three or four grains of calomel, to be followed in the morning by Glauber or other laxative salts. Milk and Vichy, or a weak solution of ammonium chloride in water (gr. lxxv to Oi), should be taken freely as a drink, and tepid douching of the liver while the patient reclines is grateful and advantageous, says the same author. Beale highly recommends a nitro-hydrochloric-acid (one to eight) pack over the liver, and others speak enthusiastically of faradization, in twenty-minute séances, especially in engorgement with jaundice. One pole of the battery should be placed over the intestines opposite the middle dorsal region, while the other pole should be passed over the right and left lobes of the liver, with occasional pauses directly over the gall-bladder. Cyr advises counter-irritation even to the extent of actual cautery in chronic cases. Ammonium chloride, according to Dr. Stewart, when taken for engorgement of the liver, will produce in a few minutes to a half-hour "a sensation as of a shock, or as if cold water were trickling down the side, or even as of pulling, clawing, or gnawing. These are favorable signs, for they do not occur unless hepatic disease be present." The only contra-indication to the use of ammonium chloride is high fever with a hot dry skin, when ammonium acetate may be profitably substituted for the muriate. During treatment Dr. Stewart confines his patients strictly to bed and limits them to small quantities of milk and farinaceous foods, with barley-water as a drink. Diarrhœa does not contra-indicate the use of ammonium chloride, for looseness of the bowels may arise from congestion of the liver, which is most promptly relieved by this salt.

Dujardin-Beaumetz's latest advice is to "place at the head of your treatment milk diet, which of itself is capable of bringing about an amelioration equivalent to a cure." Cases reported at several recent sessions of the French medical societies seem to show that such recoveries are by no means so rare as one might suppose. A favorite prescription of Dujardin-Beaumetz's is the following:

℞ Pure hippuric acid, 25 grms.;
Milk of lime (neutralized), q. s.;
Syrup, 500 c.c. or grammes;
Essence of anise (to flavor), q. s.
Mix.
Sig.—Four to six teaspoonfuls a day."

Among other formulæ which may be found useful in the treatment of hepatic cirrhosis and its complications are—

Gastric Tonic.[1]
Sodii bicarb., ʒii;
Tinct. nuc. vom., ♏xvi;
Inf. calumbæ, ℥ii.
Teaspoonful before meals.

Iron Mixture.[2]
Tinct. ferri chlor., ♏x;
Acid. acet., ♏x;
Liq. ammon. acet., ʒss;
Aquam ad ℥ss.
Pro dos. t. i. d.

Eustace Smith also advises the use of the exsiccated sulphate of iron in full doses (gr. vii in glycerin). Of mineral waters the most highly esteemed are the Carlsbad, Harrogate, and Vichy.

The action of the skin should be assisted by the use of warm baths daily, and the child properly protected from chilling by woollen underwear.

The treatment of lithic symptoms is, on the whole, satisfactory, for we agree with A. Haig that uric-acid excretion is largely under the control of the physician by means of drugs and foods, and that when uric acid is diminished relatively to urea such diminution is due to the retention of the uric acid in the liver and spleen and possibly in other organs. Increased excretion means the washing out of this retained acid: hence uric-acid migraine can be produced by increasing the acidity of the urine. Animal food increases the absolute amount of uric acid. Where there is retention, potassium iodide (gr. v) has little or no effect; in large doses it acts as an alkali. Phosphate of sodium is a good solvent of uric acid, and greatly increases excretion, because of its union with uric acid in more soluble forms. Salicylates excrete uric acid independently of acidity; colchicum lowers acidity and thus assists excretion.

Kellogg, of Battle Creek, Michigan, highly recommends rectal insufflation of oxygen in these cases. Theoretically it ought to be of great value. Empirically the writer has found the compound spirit of lavender a valuable adjuvant to other drugs for the removal of uric-acid sediments.

Hemorrhage, when alarming, may usually be checked by gallic acid, dilute sulphuric acid, or other astringents.

MALARIAL CIRRHOSIS.

Definition.—According to Lancereaux, malarial cirrhosis is a characteristic form of hepatic disease produced by malarial intoxication.

History.—The affection was first described by Lancereaux in lectures recently delivered in Paris, although the effects of malarial poison upon the liver had frequently been referred to by other authors, especially by West, who in his earlier writings calls attention to the fact that children under the influence of malaria often develop ascites with dryness of the skin and general disturbance of nutrition. Similar cases have long been known in the rice-fields of Pavia and among the poor whites of the South and others residing in malarious districts.

---

[1] Eustace Smith.

[2] Ibid.

Etiology.—The exact etiology of malarial cirrhosis can as yet only be surmised. If the existence of Laveran's bacillus malariæ be proved, and its action upon the blood-corpuscles is that described by Sternberg, it is more than probable that the products of such destruction are chemical compounds analogous to the leucomaine poisons in their action upon the liver.

Pathology.—The chief morbid changes noted by Lancereaux are great enlargement of the liver and increase in its weight, which is sometimes doubled without causing the organ to lose its normal shape. Its surface is smooth and without prominences, but the liver-tissue is increased in density to a degree a little less than that of cirrhosis produced by alcohol. Unlike this, it does not grate beneath the knife, nor has it the elasticity of alcoholic cirrhosis. A cross-section shows variable pigmentation, but the granulations do not project above the cut surface, like the larger papillæ of ordinary cirrhosis. A proliferation of connective tissue does not accompany the venous radicles of the portal system, nor does the perihepatic net-work of vessels show any evidence of endophlebitis, which, according to Lancereaux, explains the absence of dropsy due to portal obstruction, for many capillaries traverse the new connective tissue, and thus circulation is everywhere preserved.

The consistence of the connective tissue, however, rather than its arrangement, is especially distinctive of this form of cirrhosis, in which we find this tissue in its embryonic state, unlike the firm, hard, unyielding connective tissue of ordinary cirrhosis. "In malarial cirrhosis the proliferation presses only on the borders of the lobules, which thereby become fringed and irregular, but the lobule is not invaded, nor is its central vein implicated. The biliary canaliculi are extensively distended by the new growth, which leads to their greater prominence and to the chronic jaundice which is a very marked symptom. The larger bile-ducts and the common duct always remain free. The liver-cells on the surface of the lobule are compressed and elongated, and their protoplasm is diminished. In the centre of the lobules the liver-cells preserve their normal form and are filled with bile-pigments and fat-granules merely" (W. H. Welch).

Symptomatology.—The symptoms of malarial cirrhosis differ little, if any, from those of atrophic cirrhosis, beginning, like it, with dyspeptic symptoms, vomiting, and transient diarrhœa. There is often troublesome pruritus, and the skin is rough and dry. Epistaxis is prone to occur, although bleeding from the gums is more frequent. Occasionally heart-murmurs are present at the right border of the sternum, due to tricuspid regurgitation (Potain), but the respiratory sounds are unaffected. One of the rarer symptoms is hemeralopia, intermittent or variable, attributable to pigmentary deposits in the retina, first observed by Scarpa among the peasants working in the rice-fields of Pavia. This symptom occurs only in chronic cases. Delirium and fever attend the close of fatal cases of malarial cirrhosis, the patient usually dying in coma.

Differentiation.—Lancereaux clinically differentiates this form of cirrhosis by (1) its history of chronic malarial intoxication; (2) the hypertrophy of both the liver and the spleen; (3) the persistence of jaundice, lasting at times for years; (4) the color of the skin, being of a dark-brown tint rather than of the greenish-yellow hue characteristic of jaundice due to impaction. It can furthermore be distinguished from alcoholic cirrhosis (atrophic) by the great enlargement of the liver, the implication of the spleen, and the absence of dropsy in malarial cirrhosis. It may be differentiated from alcoholic fatty hypertrophy by the edges of the liver being found sharply defined in malarial cirrhosis, while fatty hypertrophy causes them to become rounded and roughened. Carcinoma with jaundice is not easily diagnosed from malarial cirrhosis except by the previous history of the case, and by the development of nodosities sooner or later in the cancerous cases.

Prognosis.—The prognosis is generally favorable to life, and hopeful for entire recovery, if the patient can be early removed from the malarious districts. The results obtained by Lancereaux in children were very encouraging, and the same is true of West's cases, which under treatment with cinchona recovered so rapidly that Birch-Hirschfeld is inclined to doubt their having been cases of true cirrhosis.

Treatment.—The treatment of malarial cirrhosis in its earlier stages is about the same as that of the usual hepatic congestion of intermittent fever, —viz., with quinine, wet or acid packs, ammonium chloride, etc. In the later stages hydropathy may be useful, and potassium iodide should be substituted for quinine and continued for weeks and months, with a rigid milk diet (Lancereaux). The author has in some of these cases obtained excellent results from syrup of iodide of iron and Fowler's solution, conjoined with the free use of buttermilk or skim milk.

SYPHILITIC CIRRHOSIS.

Synonymes.—Congenital cirrhosis; Hepatitis interstitialis syphilitica, Peripylephlebitis syphilitica, Diffuse and circumscribed syphilomata of the liver; German, Gummata des Lebers.

Definition.—An interstitial hepatitis due to syphilitic poisoning, acquired or congenital.

History and Occurrence.—Syphilitic hepatitis is one of the more frequent lesions of the liver in early infancy, though more rarely observed in older children; but it should also be remembered that, with the exception of catarrhal icterus, diseases of the liver are comparatively rare in children. Of the forty thousand sick children examined by Steiner, there were only four hundred and twenty-five cases of diseases of the liver, syphilitic hepatitis standing sixth in his list, and being noted as uncommon.

Etiology.—Hepatic syphilis belongs peculiarly to early infancy. The largest number of cases reported were found in the very earliest period of life, frequently prenatal, but at any time during the life of the child syphilis of the liver may appear.

It is a frequent cause of infant mortality, for of four hundred and ten autopsies made by Birch-Hirschfeld upon infants one hundred and twenty-four gave proof of syphilization of the internal organs, especially the liver. Specific infection, of course, lies at its foundation, and in by far the larger number of cases this is inherited from the parents. More rarely it originates from the nurse, and later in childhood there are beyond doubt well-marked cases of acquired syphilis, like those of the adult, although it is still a question in dispute whether these liver-manifestations occurring late in childhood may not be due to syphilis inherited from the parents. Dittrich gives cases of hepatitis syphilitica in children of eleven, fifteen, and eighteen years, which apparently confirm the possibility of the appearance, even at those ages, of these late syphilitic manifestations.

Pathology.—A typical syphilitic liver is dense, elastic, irregular in outline, nodulated, with increased size and density, and giving an impression of resistance above normal when cut. The color, according to Gubler, is like that of flint, while Trousseau compares it to that of sole-leather. Birch-Hirschfeld says it has all possible tints from yellowish white to dark brown.

The structure of the acini is completely obliterated, but it should be remembered that in the new-born these are normally indistinct. A closer examination with a glass often shows in the cut surface innumerable fine gray or grayish-white points and lines which bespeak a proliferation of the interlobular connective tissue. It is also to be noted that the connective tissue in the immediate neighborhood of the branches of the portal vein is thickened. The capsule of the liver shows at times, to a more or less marked degree, thickening, and may be adherent to the peritoneum or the abdominal walls, while the peritoneum itself shows proof of well-marked thickening. The gall-bladder often contains only slimy yellow masses, or, in other instances, a small quantity of brownish-green bile. If the syphilitic hepatitis be localized instead of diffuse, there will be found isolated spots of sclerosis scattered here and there through the liver; or true syphilitic gummata may be discovered as sharply-defined nodules from the size of a pea to that of a walnut, which differ in no essential particular from those met with in the other organs of syphilitic children, in whom they appear either as an acute swelling without well-marked gross alteration, except a diffuse growth of the connective tissue, or there may be diffused miliary gummata, or peripylephlebitis syphilitica,—*i.e.*, a syphilitic inflammation of the hepatic septa. According to Starr, syphilitic proliferation differs from true cirrhosis of the liver in that the former "invades the connective tissue between the hepatic islands and that in their interior as well," while cirrhosis proper affects only the connective tissue between the lobules. The bile-ducts may also be thickened and occluded with epithelial cells, especially if the case be complicated with jaundice. In these cases the volume of the liver is little if at all increased, and an incision fails to give the sense of resistance met with in general syphilitic hepatitis.

The miliary gummata previously alluded to consist of a dissemination through the liver of a large number of millet-seed dots, or gummata, which not infrequently coalesce to form knots. This is apparently a characteristic syphilitic lesion of the earliest years of childhood, and may appear either in a liver which is in the main normal or as a generally diffused miliary gumma (Birch-Hirschfeld).

Contraction of the syphilitic liver follows as a result of the retraction of these syphilitic masses of hypertrophied connective tissue. At the beginning the formation of gummata in the liver is attended with an increase in its size; this is well marked in young children; later the tissue shrinks gradually, until at last it becomes less than its original bulk.

Complications.—Perihepatitis and increase of the connective tissue of Glisson's capsule, according to Steiner, are the most frequent complications in syphilitic hepatitis. The usual dermal and visceral lesions of hereditary syphilis may, of course, be met with in these cases. Splenic enlargement is almost invariable.

Symptomatology.—There are, says Birch-Hirschfeld, no strictly characteristic symptoms of syphilitic hepatitis which are diagnostic of this complication, for, as in the adult, the morbid process may develop without any well-marked symptoms, unless a perihepatitis complicates and produces pain and tenderness. Icterus is not usually a prominent symptom, especially in the new-born child, in whom syphilitic symptoms are few and ill defined. The liver itself is irregularly enlarged and harder than normal, and may, if this enlargement is great, give rise to jaundice, as happens in all forms of hypertrophic cirrhosis from mechanical compression of the bile-ducts. Ascites occurs later, associated with marasmus and a subnormal temperature. Ecchymoses and ordinary skin-lesions of hereditary syphilis may, of course, appear. Such children, aside from these lesions, may often be suspected from their fretfulness, uneasiness, and whining without shedding of tears. They rub their legs against the abdomen until it becomes swollen and chafed. Vomiting and diarrhœa or constipation are frequent, and the pulse, as a rule, is small and weak. In fatal cases the eyes become sunken and surrounded with dark circles, the extremities grow cold, and the child dies of exhaustion.

Differential Diagnosis.—The diagnosis is differentiated mainly by the presence of syphilitic lesions other than hepatic. These being established, and hepatic incompetence or ascites existing at the same time, a diagnosis of syphilitic hepatitis can fairly be made. A mild degree of syphilitic hepatitis is, however, not easily diagnosed (Steiner), as it presents no well-marked proof of its existence either by physical examination or from the study of the child's symptoms, which are inconspicuous and not diagnostic. *Per contra*, hepatic disturbance at a very tender age, especially if accompanied by enlargement of the liver and by ascites or jaundice, should always be considered a sufficiently suspicious circumstance to direct the mind of the attending physician towards the possibility of syphilitic disease, even in the best of families.

If a perihepatitis develops, as is frequent with older children, there will be tenderness on pressure in the region of the liver, and if adhesion has taken place between the capsule of the liver and the abdominal walls the respiratory movement of the thorax will be hindered thereby; but of all the symptoms here detailed the only one which is absolutely constant is the irregular enlargement of the liver. This is often great, and is recognizable as a perceptible swelling of the right hypochondrium. The lower border of the liver may extend to the navel or beyond, and may appear irregularly nodulated or more rarely symmetrically increased in size, yet it is not so much the changes apparent in the liver as their location which enables us to make a reasonable diagnosis of syphilitic hepatitis, whose lesions occur chiefly as neoplasms about the larger bile-ducts and the roots of the larger vessels of the liver (Birch-Hirschfeld).

Prognosis.—Steiner and the majority of foreign writers in general, except Goodhart, incline to a gloomy prognosis as regards the cure of syphilitic hepatitis; and yet permanent cures are by no means infrequent. The writer's experience is that of Goodhart, who states that the majority of such cases, except in the very youngest children, are remarkably amenable to mercurial treatment. Profound cachexia, pernicious jaundice, ascites, and hemorrhage are unfavorable symptoms, and are almost invariably precursors of death.

Icterus depending upon congenital syphilis is usually grave, but not invariably so, for Jacobi reports several such cases which recovered.

Treatment.—Mercurials are of the greatest value in these cases, combined with the internal use of tonics, cod-liver oil, etc., unless contra-indicated by diarrhœa. Nutrition must be especially looked after, as early syphilis produces general depression of the vital forces: hence the imperative necessity for tonics and a full supply of good and easily-digested food. Of mercurials, preference is usually given to the mild chloride, one-twentieth to one-eighth of a grain of which may be administered in sugar of milk to nurslings twice or three times a day, until contra-indicated by looseness of the bowels; then mercurial inunctions (gr. x–xx well rubbed into the skin daily, or applied upon a flannel binder) will be found efficient, though uncleanly. Later the syrup of the iodide of iron (gr. v–xx) is excellent. Starr recommends iodide of potassium with ammonium chloride in J. Lewis Smith's mixture:

℞ Potass. iodidi, gr. xxiv;
Ammon. chloridi, gr. xxxvi;
Syr. sarsap. comp., ℥ss;
Aquæ, ℥iii.
S.—Teaspoonful three times a day.

or the following:

℞ Hydrarg. bichlor., gr. ss;
Potass. iodidi,
Ferri et ammon. citrat., āā ʒ i;
Syrupi, ℥ vi.
S.—To a child from three to five years old.

Splenic enlargement yields more slowly to treatment than do hepatic complications in syphilis of children. External applications, as ammonium-chloride lotions or dilute compound tincture of iodine ointment (one to seven, Starr), will hasten a cure.

J. Lewis Smith prefers minute doses of the bichloride with iodide in the prescription previously given. Otis prefers blue mass long continued. R. W. Taylor prefers the bichloride in compound syrup of sarsaparilla, as do also G. H. Fox and W. H. Draper. Jacobi advises that the mercury should be given for a long time, by the administration of a twentieth or a twelfth of a grain of calomel three times a day; or by careful inunction of a scruple of blue ointment daily; or by the subcutaneous injection of one-thirtieth of a grain of corrosive sublimate in a one-fifth of one per cent. solution of distilled water daily. In the beginning of the treatment two of these medications may be combined, or one of them may be accompanied by the internal administration of from three to five grains of iodide of potassium. The internal administration of the bichloride of mercury is also well tolerated; one-hundredth of a grain may be given in a teaspoonful of water, or food, every two or four hours, and continued many weeks, for a thorough and energetic antisyphilitic treatment is the only safeguard in this disease. And yet treatment often fails, because the syphilitic lesions are not confined to the liver, but extend to the connective tissue of other organs as well.

ACUTE YELLOW ATROPHY OF THE LIVER.

Synonymes.—Typhoid icterus, Hemorrhagic icterus, Malignant jaundice, General parenchymatous hepatitis (Bartholow); French, Atrophie aiguë du foie, Ictère grave, Hépatite maligne.

Definition.—An acute, degenerative inflammation of the liver, resulting in arrest of its functions and in death from toxæmia. Steiner would still further limit it to those cases in which an abundance of both leucin and tyrosin may be found in the urine.

History and Cause.—So far as the writer is informed, the first account of the occurrence of this rare disease in children is that given by Dr. Loeschner in 1859 in the *Allgemeine Medicinische Central Zeitung*, No. 68. Bouchut speaks of cases which had come under his observation, in some of which recovery took place, but there is no mention of acute yellow atrophy in children by many of the leading writers on pediatrics.

Among adults this disease is more frequently met with in females than in males, but yellow atrophy is so rarely observed in children that it may practically be excluded from their usual diseases.

Dr. H. Greeve, however, reports a recent case, in the *Medical Press and Circular*, April 30, 1888, of a boy aged twenty months who had suffered from jaundice when fifteen months old. Two months later he had another attack, and died the nineteenth day thereafter, with a temperature of 108° F.

Etiology.—Twenty years ago the investigations of Oscar Wyss (1868) proved that catarrhal jaundice might be due to a catarrh of the bile-ducts, chiefly in their proximal extremities, the obstruction occurring near their origin. This is fully in accord with Chaufard's theory that jaundice is often due to an accumulation of irritant substances in the liver, which beget an irritation of the hepatic ducts, beginning at their origin. These irritant substances may be and often are the leucomaines and ptomaines, whose effects upon the liver have been carefully studied by Gauthier, Schiff, and Lauterbach. The accumulation of these substances in the blood, together with its disintegration, is, to the mind of the writer, a more probable cause than the large number of others which have been offered as the efficient ones in the production of acute yellow atrophy, among which may be mentioned excess of bile, stasis of bile, cholesteræmia, with anger and violent passions, etc., as predisposing factors. As yet the exact etiology of this disease is not fully understood, but it seems to the writer that Budd and Bartholow are not far from the truth in their suggestion that its cause lies in a blood-poison, of as yet unknown nature, which acts specifically upon the liver-cells and destroys their further action. This hypothesis is well borne out by the fact that phosphorus, antimony, or arsenic when introduced into the system in toxic doses may produce symptoms clinically so nearly like those of acute yellow atrophy that they cannot be differentiated from it without the previous history of the case. According to Rendu, even subacute alcoholism under certain circumstances may do the same. In these cases we know that a specific poison circulating in the blood produces these changes in the liver and resulting toxæmia. By analogy it is fair to conclude that some other poisonous substance produces the closely resembling symptoms and pathological changes of idiopathic yellow atrophy. The writer strongly suspects that this poison, or these poisons, will be found closely related to the leucomaines more fully discussed under the head of atrophic cirrhosis, the jaundice in all probability being directly derived from the decomposition of the red corpuscles,—*i.e.*, hæmatogenous.

Pathology and Pathological Anatomy.—Bartholow gives the pathology of this disease as that of an acute, diffuse, parenchymatous hepatitis. The liver is considerably atrophied, and flattens by its own weight, has a uniform yellow color, and is readily friable. Its peritoneal surface is roughened and wrinkled. Microscopically it shows a primary stage of hyperæmia, congested loci persisting even after the rest of the organ becomes anæmic. A grayish-yellow substance is deposited between the lobules and increases the interlobular spaces. Albuminous and fatty matter mixed with pigments is deposited in the cells, and where these have become disintegrated there is found fatty brown granular matter. The finer branches of the hepatic artery and portal vein in this way become obstructed. The blood contains considerable leucin and urea. The spleen is usually, though not invariably, increased in size. The endothelium of the lobules of the kidneys is deeply stained with bile and infiltrated with granular matter undergoing fatty degeneration, and the muscular tissue of the heart undergoes similar changes. The urine at first is normal in quantity and of the usual specific gravity, later the urea and the phosphate of lime are diminished and replaced by leucin and tyrosin. Ecchymoses and petechiæ are often found upon the skin.

Symptomatology.—In the adult acute atrophy begins insidiously, often like a simple gastro-duodenal catarrh, with epigastric tenderness and slight jaundice. The pulse and temperature at first vary but little from normal, but in from a few hours to a fortnight the temperature rises, insomnia and headache appear, and toxæmia begins, with cerebral symptoms. The pulse is now very rapid (140), but with great variations, often falling to 70 or below, and thus fluctuating several times in a day. There is an evening exacerbation (104° F.) and a well-marked morning remission (102°). Jaundice increases. Sometimes there are brownish patches and the breath is fetid, the tongue dry and brown, and the teeth covered with sordes. Nausea and vomiting are troublesome, and pain is sharp upon pressure over the liver, which is distinctly smaller. Tarry passages take place from the bowels, and a coffee-ground vomit may occur, due to internal hemorrhage.

In other cases the children have been attacked with high fever at the beginning, with hepatic pain, enlargement of the liver, well-marked icterus, considerable prostration, some epistaxis, purpura, or hæmatemesis, and melæna (Bouchut).

With young children (from two to four years old), says Loeschner, the disease may easily be mistaken for meningitis, from the close resemblance of their symptoms; with children from seven to twelve its course is more like that of typhoid fever (see Differentiation), especially in its final stage of great nervous irritability and restlessness, followed by noisy delirium soon passing into a low muttering form and terminating in death from coma, or convulsions.

Differentiation.—The differentiation of acute atrophy is not easy, both because of its complications and because as yet there is no definite agreement among writers as to exactly what constitutes acute atrophy. The physical signs of a shrunken liver, fever, headache, and insomnia, with the occurrence of leucin and tyrosin in the urine,—if these be considered diagnostic,—ought to be sufficient to establish a diagnosis; but the disease is a rare one, and undoubtedly is frequently overlooked in adults, and perhaps also in children. In all suspicious cases examinations should be made for leucin and tyrosin. These, when present in urine, may be easily recognized by evaporating it to a small bulk and allowing the salts to crystallize spontaneously, when leucin may be recognized under the microscope in brown oily layers and tyrosin by its sheaf-like bunches of needles. Frerichs's method is more tedious, and consists in precipitating the urine with acetate of lead, filtering, removing the lead from the filtrate with sulphuretted hydrogen, refiltering, and evaporating the filtrate to a small bulk on a water-bath. From this concentrated filtrate tyrosin and leucin separate spontaneously as above.

Meningitis, according to Bouchut, often coexists as a complication, caused by the original malady of the liver. In such cases the result obtained from the physical examination of the liver, conjoined with other salient symptoms, ought to enable one to recognize the hepatic disease as the fundamental one.

Acute yellow atrophy may be differentiated from typhoid by the slowness of the pulse (60 to 70) in the initial stage of acute yellow atrophy and by the more or less intense yellow coloration of the skin observed therein. Moreover, pains are complained of, at first in the right hypochondriac region, thence spreading at times into the shoulder or just below the shoulder-blade.

The liver in fatty degeneration is not appreciably softened, and is somewhat diminished in size, but in simple fatty degeneration there is no leucin nor tyrosin found in the urine or in the liver, but only in numerous fat-cells instead. But in extreme cases of fatty degeneration differentiation is almost impossible.

In severe cases of fatty degeneration the urine is loaded with bile-pigments and acids, and the cases end fatally with mania, convulsions, and tetanic spasms. In such cases extravasation of blood under the skin or mucous membranes is liable to occur, and differentiation is almost impossible (Steiner).

Prognosis.—The most favorable report found is that of Bouchut, who says, "Death is the usual result in this disease, which may, however, terminate favorably." The general rule, however, is that a fatal result is arrived at within a week : there are exceptional cases in which the prodromal stages last a couple of weeks, though, as a rule, death ensues within five days after the development of high temperature and insomnia. It is doubtful if there is any well-authenticated case of recovery from acute yellow atrophy in children, unless it may have occurred in some of the milder forms of phosphorus-poisoning, and in these, in all probability, the supposed yellow atrophy had not proceeded further than simple re-absorption jaundice, for it is difficult to perceive how liver-cells after they have become disintegrated may be restored (Bartholow). The progress of the disease is irregular, and the duration of the preliminary stage of icterus is uncertain, but the closing toxæmic stage almost uniformly terminates fatally within five days.

Treatment.—Bouchut's treatment consists of "the free use of emollient or diuretic drinks containing bicarbonate of sodium or acetate of potassium :

this, with the application of several leeches over the liver at the beginning of the disease, is the only thing of value in the way of medication." The child should be fed with soups or milk (diluted), and if there is sharp pain the application of poultices containing laudanum may be useful.

Except Bouchut's, the writer as yet has been unable to find an account of a case of yellow atrophy successfully treated in a child. Frerichs claims to have cured one in the adult with purgatives and mineral acids, the use of which in children would be of course justified by such undoubted authority. On theoretical grounds, the early internal use of the salicylates might be of value.

Bartholow recommends the use of morphine before the liver-cells begin to disintegrate, after which alcoholic stimulants should be pushed to their fullest extent. The use of minute doses of phosphorus has not been followed by any beneficial results, although advised by high authority.

ASCITES.

Synonymes.—Abdominal dropsy, Dropsy of the peritoneum.

Definition.—Abdominal transudation of fluid into the peritoneal cavity, due to interference with the hepatic circulation caused by cirrhosis of the liver or other agencies which produce pressure upon the portal circulation.

Varieties.—Passive, peritoneal, obstructive, etc.; but it should be remembered that an accumulation of serum in the peritoneal cavity is never a primary disease, but only a symptom of general dropsy or of some local affection of the abdominal cavity.

Etiologically, Steiner divides ascites into (*a*) hydræmic, (*b*) mechanical, or that arising from obstruction of the venous circulation by cardiac, pulmonary, or peritoneal lesions, and (*c*) neoplastic, or that due to abdominal tumors, cancerous or otherwise, especially lymphatic tumors, more commonly located in the hepatic notch.

Etiology.—Dropsy is not *per se* a disease, but is a symptom common not only to syphilitic or other disease of the liver in childhood, but also to other disorders of the circulation, and to hydræmic disease of the peritoneum. In the adult, general dropsy is perhaps most frequently due to renal disorder; in the child, to cardiac lesion, especially of the tricuspid valve (Kormann). Such pulmonary diseases as atelectasis or emphysema are not infrequent causes of ascites, but syphilitic gummata and pylephlebitis of the liver are its most frequent causes in children, so much so that the appearance of ascites in the child without other known cause always justifies resort to antisyphilitic remedies as an aid to diagnosis. Again, it may arise from splenic enlargement caused by malarial poison, or, as in the adult, it may be a symptom of Bright's disease or of the nephritis following scarlet fever. Furthermore, the pressure of infiltrated or waxy lymphatic glands upon the vena cava inferior or the portal vein may cause ascites. Again, ascites is found accompanying hydrothorax and the general œdema due to hydræmia. Lastly, ascites—though more rarely than that from previously mentioned causes—may be due to tuberculosis of the peritoneum, which causes a chronic peritonitis and consequent obstruction of the peritoneal circulation.

Grancher asserts that if the fluid is localized in one part of the abdomen, immovable, and not excessive in quantity, it is probably due to tubercular peritonitis, especially if there is evidence of tubercular trouble elsewhere; though, as a rule, ascites and tubercular peritonitis do not coexist. Excluding cardiac and renal lesions, which are comparatively infrequent in childhood, by far the most frequent cause of ascites in children is cirrhosis of the liver, which may always be suspected when the fluid is large in amount and movable (Terillon).

Pulmonary troubles rarely give rise to ascites in young subjects, and the same is true of interstitial nephritis, which is more prone to result in general anasarca. Profound anæmia may cause ascites, but this is infrequent except as a complication in profound malarial poisoning. (See Malarial Cirrhosis.)

Pathology and Pathological Anatomy.—The pathology of ascites can be better understood if it is remembered that its primary lesions exist either in the peritoneum or in some obstruction to normal circulation through the portal veins, due to gummata, cancerous growths, hydatids, or cirrhotic change in the liver or kidneys, etc.

According to Terillon, serous effusions in the abdominal cavity may be due to one of two distinct conditions of the peritoneum,—viz., (*a*) the peritoneum is reddened and velvety in appearance, or (*b*) the peritoneum is pale and shows no trace of inflammatory action. Quinn thinks such ascites is due to a peculiar condition of the peritoneum, which is found covered with inflammatory granulations and looks as if sand had been strewn over it.

The presence of ascites with tumor suggests the malignant character of the latter; but ascites may also coexist with benign tumors, though such cases are exceptional.

Complications.—Collapse of the base of the lungs is by no means an infrequent complication. Next in frequency ought perhaps to be mentioned œdema of the feet and ankles, caused by the presence of the fluid in the abdomen. Peritonitis, if present, gives its usual post-mortem appearances, previously described. Splenic enlargement may be expected when the ascites originates in cirrhosis of the liver.

General anasarca occurs as a complication in ascites according as the results of vascular congestion are confined to the peritoneum or not (Caillé). As a result of large effusions, the liver, spleen, and kidneys may become anæmic, the secretion of urine diminished, and the diaphragm crowded up to the second or third rib. Œdema of the ankles, limbs, and genitals may ensue.

Symptoms.—There are no characteristic prodromal symptoms of ascites, though an effusion of fluid into the peritoneal cavity may be preceded by chilliness, headache, vomiting, abdominal pain, emaciation, and spasmodic attacks of diarrhœa lasting for a day or so (Eustace Smith).

Ascites, as a rule, is not painful, unless it proceeds from peritonitis. Indigestion and irregularity of the bowels, as might be expected from the abdominal tension, are generally present in such cases. The skin is dry and of an earthy tint. The physical signs are those of a mobile fluid in the abdominal cavity, whose examination ought to be painless. Ascitic fluid changes its position with gravity : hence the abdomen will be noticed to be largest below while standing. When the child lies on its side, the abdomen spreads out laterally and gives a characteristic sense of fluctuation or undulation. Small effusions are more easily detected in the sitting or in the lateral position, but often are found with difficulty even then. Large effusions render the skin of the abdomen tense and shining, and sometimes produce the striæ of hyperdistention seen upon the abdomen of a pregnant woman. The navel is often protuberant, and may be surrounded by a net-work of dilated veins, known as the caput Medusæ. The temperature remains normal unless some inflammatory complication is present. The urine is variable in amount, often scanty, high-colored, and containing albumen and fibrinous casts.

Increasing abdominal pressure at last renders the passage of fæces difficult and produces dysuria, or incontinence of urine. Continued upward pressure of the diaphragm, which may be found as high as the second or third rib, causes dyspnœa, often aggravated by hydrothorax, until death results, either from exhaustion or from asphyxia, the child at last being unable to lie down at all.

Differentiation.—A case of ascites to which the tests of palpation and percussion can be successfully applied could hardly be mistaken for anything else, but it should be remembered that a protuberant abdomen from other causes than ascites is often met with in children. On the other hand, a moderately large effusion is necessary to distend the cavity sufficiently to give clearly the physical signs of fluctuation. Fluctuation—or, rather, undulation—may best be recognized by placing one hand open against the abdomen and tapping sharply with the fingers on the opposite side of the abdomen. An abdomen filled with serum ought to convey a wave-like impression to the outspread hand. Percussion over the most prominent part where the intestines float highest gives a clear percussion-note which alters its position with that of the patient. If the child lies on its back the lower and lateral regions of the abdomen give a dull percussion-note. This, and the peculiar mobility of the percussion-note already mentioned, usually serve to clear up the diagnosis.

Prognosis.—Differentiation as to the etiology of the ascites is often valuable in the way of prognosis. That form of cirrhosis which produces ascites is mainly the atrophic variety, which, consequently, gives us a liver diminished in size. Disseminated nodules characterize tubercular peritonitis, in which there are usually tenderness upon pressure, fever, and pain.

The prognosis is not necessarily hopeless, though in general discouraging. If the primary cause of the ascites is removable, as malaria or alcoholism, and only a limited portion of the liver is affected, it is not unreasonable to hope that the entire removal of the cause, with intelligent hygiene assisted by proper medication, may effect a cure if the quantity of the fluid oozing from the peritoneal surfaces is small and the collateral circulation is fairly preserved.

Goodhart believes that in tubercular peritonitis the prognosis is better for the child than for the adult, as proved by the post-mortem table.

Medical Treatment.—If the ascites is slight, administer such diuretics as acetate of potassium, juniper-berries, or infusion of digitalis. If there is no heart-lesion, try fluid extract of apocynum cannabinum. When anasarca complicates, try the sweating cure as recommended for scarlatinal dropsy, with a strict milk diet conjoined. Tonics, iron, and good air are indicated where there is concomitant hydræmia.

In the ascites of atrophic cirrhosis Hurd highly recommends a pill composed of equal portions of squill, digitalis, and calomel.

Ordinary diuretics have little effect upon this form of ascites, in which E. Smith highly recommends the use of Basham's iron mixture. (See Cirrhosis.) If this fails and the fluid continues to accumulate, recourse must be had to the surgical treatment of ascites. W. H. Thompson and others advise that this should be adopted early, believing, with Dujardin-Beaumetz, that in the majority of cases diuretics, and especially purgatives, have no effect in removing the abdominal effusion, and that, for obvious reasons, when these medicines are too long continued the general condition of the patient is injured rather than improved: nevertheless, Dujardin-Beaumetz delays tapping as long as possible, resorting to it only for relief of threatened asphyxia.

Surgical Treatment.—Interference with the action of the diaphragm ought to be a sufficient reason for mechanical relief from dropsy by tapping. It carries with it slight, if any, danger to the child, and may be accomplished by the aid of the aspirator or a fine trocar, and repeated as often as required. Dujardin-Beaumetz's rule in regard to tapping is that if the subject is young, vigorous, and possesses good digestion it is wise to tap early, but even in such cases if refilling takes place rapidly—say, in three or four days—retapping should be delayed as long as possible; while if it takes two or three weeks for the peritoneal cavity to become full again, paracentesis may appropriately be repeated at the end of that time. The operation is simple and safe, provided two precautions are taken,—viz., first of all, be careful as to the place where you make your trocar-puncture, in order to avoid wounding any enlarged or distended veins, which in the cirrhotic ramify abundantly upon the abdominal wall; secondly, after the tapping is terminated see to it that the patient lies on the side opposite to that where the puncture was made, and that he keeps that position for some time, in order to enable the wound to cicatrize. You will thus avoid those fistulæ which often remain behind, and which are exceedingly disagreeable, for they soil the patient's linen and produce cutaneous inflammation.

A. Caillé highly recommends permanent drainage by means of a rubber tube and proper antiseptic precautions whenever in ascites the fluid rapidly accumulates after one or two tappings. The number of successful cases on which he bases this advice is as yet too small to do more than encourage, but they are sufficient to justify recourse to this method when all other measures are apparently hopeless. Very remarkable results are reported by the German physicians of a similar operation in tubercular peritonitis in the adult.

PART II.

DISEASES OF THE GENITO-URINARY ORGANS.

ANOMALIES OF THE KIDNEY:

NUMBER, FORM, AND POSITION.

By GEORGE B. FOWLER, M.D.

LIKE many other organs, the kidneys are subject to variations as regards *number, form, size, position,* and *mobility.*

Such anomalies are not necessarily conducive to disease of these organs, and have, therefore, until quite recently been matters largely of anatomical curiosity. Now, however, since abdominal surgery has made such successful strides, and since some of these conditions are known to produce certain hitherto uninterpreted symptoms, the subject at once assumes great importance.

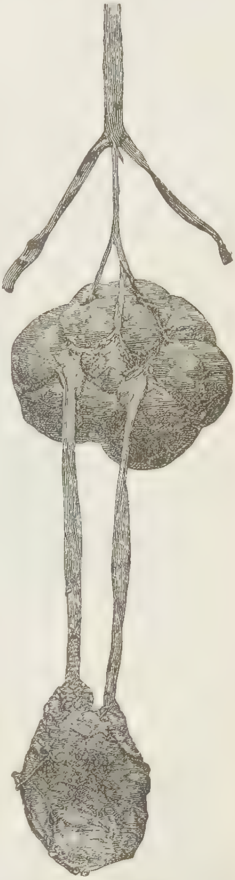
NUMBER AND FORM.

Anomalies of number and form are generally associated. In very rare instances one or two supernumerary kidneys have been discovered, each being provided with a separate ureter. Rayer, quoted by Roberts, has seen in still-born infants entire absence of both kidneys, ureters, and bladder. This observer thinks that acephalous monsters most frequently present this peculiarity.

The existence of only one kidney has quite often been observed. This state of things is due in some instances, it is thought, to the great mobility of the embryonic element of the organs, and to their tendency to fuse when in contact; and complete or extensive fusion gives the appearance of a single organ. If the fusion is extensive, and has occurred at an early period of fœtal life, the resulting organ may bear more or less resemblance to the normal one; but is lobulated, globular, and generally displaced, lying in the median line, on the spinal column below the bifurcation of the aorta, on the promontory of the sacrum, or even lower down in the pelvis. Such a kidney generally has two ureters (Fig. 1), and its blood-vessels present anomalous arrangements.

The real single kidney exists as the result of congenital atrophy of its fellow. The remaining organ then takes on an overgrowth, and is often displaced downward, perhaps on account of its increased weight. Such kidneys, the "unsymmetrical," may lie in the pelvis or iliac fossa of the same side. The ureter of the missing kidney may be entirely absent, or may be present in the shape of a rudimentary canal with its upper extremity blind and buried in the connective tissue of the surrounding parts. Some instances have been cited where there was imperfect development of the generative organs on the same side as the absent kidney, —the vas deferens, testicles, and seminal vesicles or the uterine appendages. Roberts cites a case of epilepsy observed by Dr. Leech, where solitary kidney was associated with double uterus and vagina. From the above description it is apparent that the fused kidney, although appearing so, is not really a single organ, and a solitary kidney, strictly speaking, exists only in those instances where its partner has suffered congenital atrophy.

FIG. 1.



Fused kidney taken from a child three years old, dead of pneumonia, at the New York Infant Asylum.

This latter is a rare occurrence. Beumer[1] in 1878 collected forty-eight cases, and it is estimated that not more than seventy or eighty have been reported up to the present time. Out of eleven thousand nine hundred and seventy-eight autopsies made at the four largest London hospitals, only three instances of marked atrophy of one kidney were observed.[2] This is a proportion of about one in four thousand. Of Beumer's forty-eight cases twenty-six were healthy. They were all enlarged. Four of the individuals were between forty and fifty years old. Thus it is seen that a single kidney may properly perform the function of two for many years without giving rise to any symptoms referable to the anomaly. But all statistics show that disease is very apt to exist in about one-half of the cases of single kidney, whether fused or real. Especially is calculous impaction common. These facts complicate the question of surgical interference. Added to this liability to disease of the kidney is its tendency to be displaced, and, not being recognized in its abnormal position, it may be removed. Polk[1] published such a case, the patient surviving eleven days, with no kidney at all, and with complete anuria. Roberts[2] collected twenty-nine cases of solitary, or unsymmetrical, kidney, of which the following is an analysis: "Twenty-two were males, six females, and in one the sex is not stated. One was a male infant seven days old; another, a boy of seven years; two of the cases were fifteen years old; four were between twenty and thirty, three between thirty and forty, four between forty and fifty, two were sixty, and one was sixty-five; the remainder were adults whose age is not specified. The left kidney was absent in sixteen cases, and the right in twelve; in one the side is not mentioned. In nineteen the defect was congenital; in three it had been acquired later in life, through destruction of the opposite organ; while in seven it is left uncertain whether the defect was congenital or acquired. The renal vessels and the ureters were always absent in the congenital cases." In twenty-four cases in which the cause of death is given, ten were due to impaction of calculus.

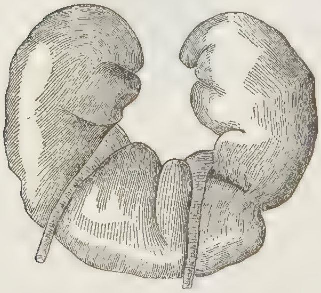
[2] Ransohoff, Hand-Book of Medical Science, Wood, vol. iv. p. 300.

Fusion of the two kidneys, as has been intimated, may exist in various degrees. The union may take place at the two lower extremities, in the middle, or at the upper borders. When united at either of the extremities the "horseshoe" kidney is the result. This, indeed, is the most common of the anomalous varieties as regards form. The uniting bond may consist of connective tissue, or, what is more generally the case, of true glandular substance.

The prevailing rule is that the kidneys thus joined are united at their lower extremities, and have two ureters which usually pass over in front of the connecting isthmus. The two organs lie close up to the spinal column, and are displaced downward.

FIG. 2.



Horseshoe kidney from an infant.

Fig. 2 represents a horseshoe kidney taken from an infant four months old, by Dr. F. M. Warner, at the New York Infant Asylum. The child had pertussis and died in convulsions. No urinary disturbance was evident. "Horseshoe" kidneys were found nine times in fourteen thousand three hundred and eighteen autopsies made at St. Bartholomew's, Guy's, Middlesex, and Great Ormond Street Hospitals, and only one completely fused kidney, other than horseshoe-shaped, in eight thousand one hundred and seventy-eight inspections.[3]

[3] Ransohoff, loc. cit.

SIZE.

Marked variation in the size of the two kidneys (otherwise normal) is sometimes observed, and is due, no doubt, to a difference in the size or number of the renal arteries supplying each organ.

URETERS.

The number and arrangement of the *ureters* are subject also to departure from the normal type. Fig. 3 represents a double ureter of the left kidney, found in an infant at the New York Infant Asylum, the two ducts reuniting about half an inch above their entrance into the bladder. Three such instances of anomalous ureters were detected by the house physician, Dr. Davis, in about twenty successive autopsies. Analogous cases have been published by Sir Henry Thompson,[1] Dr. Kelly,[2] and Mr. Wood,[3] and are cited by Roberts.[4] Occasionally one or both ureters may be partially or completely impervious, either from coalescence of their walls, when they

resemble fibrous cords, or from the formation of constricting rings of fibrous tissue.

POSITION.

We have already seen that abnormalities of number, shape, and size of the kidney are usually associated with displacement of the organ. We shall now speak more especially of malpositions of otherwise essentially normal kidneys. They are of two kinds: fixed and movable.

FIXED MALPOSITIONS.—This condition may be acquired or congenital. Pressure of new growths in the abdominal cavity or enlargement of the liver or other contiguous organs is sufficient to push one or both kidneys out of place in various directions and hold them thus. Under such circumstances they are very apt to confuse the diagnosis, and in adult females to complicate labor.

Congenital fixed malposition of the kidney has been not infrequently observed, and such an organ is generally more or less malformed. Displacement of the large intestine and peritoneum is also usually coexistent. It has been noted that the suprarenal capsules never follow the kidney in congenital displacement, but remain in their normal places.

Examples of this kind of malposition have been described by a number of writers, and Roberts[1] has collected from these sources twenty-one cases showing that only one kidney was ever displaced, and that in the majority it was the left,—fifteen to six.

David Newman[2] has contributed a very complete study of malpositions of the kidney, and Dr. W. P. Northrup[3] has described two cases of congenital fixed malpositions which were discovered by him in five hundred and fifty autopsies at the New York Foundling Asylum. As these very fully represent the anomalies of position, shape, vessels, and ureters characteristic of this class, we reproduce their histories:

"One history will serve for both: both were females; both three months old; both inmates of the New York Foundling Asylum; both died of chronic gastro-intestinal catarrh in a wretched condition of emaciation; both were without symptoms referable to the urinary tract. In one the malposition was of the left kidney. Both were found in the same month.

"Malpositions and abnormalities were as follows:

"*Case I.* (Fig. 4).—Suprarenal glands both in normal position, without reference to kidneys.

"Right kidney in normal position, its vessels of normal distribution.

"Left kidney. Its superior margin on a level with inferior margin of right, lying mostly in hollow of sacrum, perhaps one-eighth extending above the prominence. Kidney firmly attached by vessels and connective tissue.

[2] Glasgow Medical Journal, August, 1883.

[3] American Journal of Obstetrics, February, 1884.

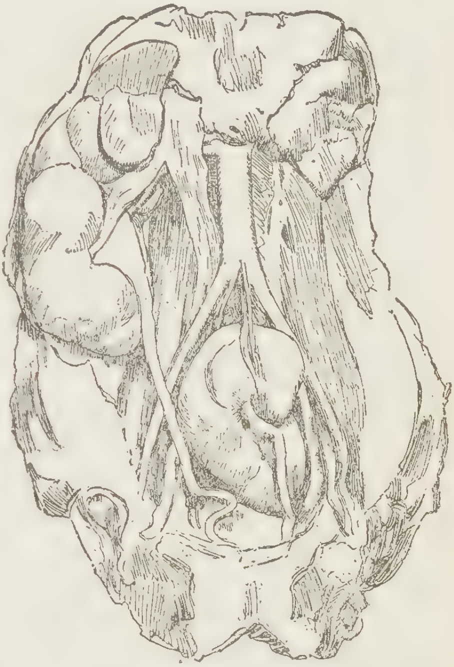
"*Arterial Supply.*—(1) Small artery given off from angle of bifurcation of aorta entering kidney posterior to and to the right of upper end. (2) Small artery arising on anterior aspect of aorta and just above the bifurcation, which reaches the hilum after passing through a groove on anterior surface of kidney. (3) Much larger artery given off from internal iliac just below its origin (not seen in cut), which passes by a short course into the hilum.

"*Veins.*—One leaves the hilum in the same groove by which artery (2) reaches it, passes under the bifurcation of the aorta, and joins the vena cava.

"*Ureter.*—About half the length of the right, its arrangement normal.

"*Case II.* (Fig. 5).—Right kidney in normal position, surmounted by its suprarenal gland.

FIG. 4.



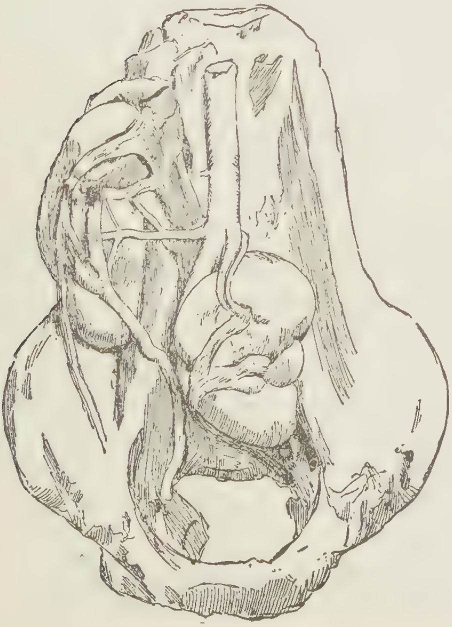
"In each kidney there is a double hilum, or two distinct, each supplied with its own arteries, veins, and ureter.

"*Arteries.*—One given off from aorta just above its bifurcation, itself bifurcates; one branch going to each hilum. This passes in front instead of behind the great vein.

"*Veins.*—(1) One from the upper hilum going directly to the inferior vena cava. (2) An anomalous vein which sweeps up from the iliac fossa over the kidney, receiving a branch from each hilum and one from surface of kidney.

"Left kidney. Position of suprarenal gland not noted. Kidney is situated one-half above, one-half below the prominence of sacrum in the median line.

FIG. 5.



"*Arteries.*—(1) Small, arises from angle of bifurcation of aorta, passes to lower hilum through a deep groove on inner side of kidney (not shown in cut). (2) Moderate-sized, arising from anterior aspect of aorta just above its bifurcation, itself bifurcates, one branch going to upper hilum, one to extreme upper end of the organ. (3) Two small arteries given off from internal iliac, reaching the lower hilum by way of two deep grooves.

"*Veins.*—(1) Small vein, companion of artery (2) above described, arises from two sources, upper hilum and extreme end of the kidney, passes behind the aorta, and joins the great vein just above the junction of the two iliacs. (2) A vein from lower hilum, winding around in a deep groove, finds its way to the vein of the common iliac."

MOVABLE KIDNEYS.

Mobility of the kidney, like the anomaly just described, may be either congenital or acquired.

The former are extremely rare, and are usually caused by some abnormality of the peritoneum in its relations to the organ, and irregularity of the vascular connections.

FLOATING KIDNEY.—The ordinary movable, or floating, kidney is much more common than is generally recognized. But whether it is acquired or congenital, it seems to me, is not always easy to determine. For its existence may not give rise to any symptoms, and may be discovered only at the autopsy. The old writers were evidently aware of this condition, but gave no comprehensive accounts of it. Within the last thirty years, however, there have been many contributions to the subject, and the latest authors all prove that floating kidney is not a very rare anomaly.[1]

From seventy cases collected by Roberts, a number of which were his own, he makes the following analysis, which, we may say, is in accord with that of all authorities. Of these seventy cases sixty-one were women and nine were men. As regards the kidney affected, sixty-five cases only are available: in forty-two it was the right, in nine the left, and in fourteen both. The ages were from sixteen to sixty-five, and the greatest number between twenty-five and forty.

Etiology.—In endeavoring to explain the cause of floating kidney several plausible views have become classical. Cruveilhier considered tight-lacing to be a frequent cause of displacement of the right kidney, on account of the displacement of the ribs and liver thus induced. But, though this pernicious practice may be held accountable for some instances, and though the great majority of cases occur among women, this is not an all-sufficient reason. For it is among females of the middle and lower, or laboring, classes where the displacement is most frequently encountered,—in those who bear the most children and do not wear stays. Most writers lay great stress upon the influence of pregnancy, and point to the fact that the majority of cases occur, in the first place, in women, and, secondly, in them at the child-bearing periods. Accidents of various kinds, too, are thought sufficient to account for a certain number of cases, such as heavy falls, blows upon the abdomen, etc. Among other causes are emaciation, with absorption of the fat about the kidney, and consequent weakening of its attachments; general relaxed condition of the walls of the abdomen, as a result either of frequent pregnancies or of constitutional vice; and, finally, Becquet[1] believes that the associated congestion of the kidneys recurring at each menstrual period frequently determines their mobility in women. It is not known that such congestion does take place, although Dr. Roberts[2] found increase of sensitiveness and apparent increase of size during menstruation in a patient whose movable kidney he was easily able to grasp.

---

[1] A comprehensive account of the literature of this subject is given by Roberts in Reynolds's System of Medicine, vol. iii. p. 737.

Bearing upon this point of etiology, the deductions of Dr. David Drummond,[3] which are contained in a very recent and timely article, are of decided value. This author narrates thirty-one cases, all of which came under his own observation, and in which he was unmistakably able to diagnose movable kidney. (But he is careful to say that he does not regard every kidney which presents a certain degree of mobility as a "floating kidney," employing the term to denote a condition of true mesonephron,—which he believes to be very rare.) Of these thirty-one cases twenty-five were women, four men, and two children, both girls. The ages of the females ranged from sixty-six to ten, of the men from fifty-six to twenty-three. Sixteen of the women had borne children, nine had not. Of the sixteen mothers nine had three or less than that number of children, and only five had large families. In eleven of the thirty-one cases there was decided emaciation. But the author very aptly remarks that the emaciation may have succeeded (and probably did) the nervous and digestive disorders so commonly associated with the displacement. Of this series the right kidney was affected in fourteen instances, the left in two, and both in fifteen. Finally, Dr. Drummond thinks that movable kidney is usually associated, without doubt, with a congenitally relaxed condition of the peritoneal attachments, and that the final displacement is determined by any of the various causes generally enumerated, together with another which he would emphasize,—viz., violent descent of the diaphragm, as in vomiting, sudden physical exertions, and asthmatic attacks.

Symptoms.—The symptoms are pain, dragging, burning, and lancinating, generally referable to the region of the displaced kidney, and radiating from the back through the abdomen, the groin, and down the thigh and leg. There are frequent attacks of headache, and marked hypochondria is common. Disorders of digestion are very prominent symptoms, and the patient, if a woman, usually considers herself to be suffering either from "dyspepsia" or from "womb-complaint." In this the doctor too frequently acquiesces. There may be intermittent attacks of hæmaturia and albuminuria, from congestion of the kidney induced by twisting of the renal vessels. Or there may be partial suppression of urine, from twisting of the ureter, inducing perhaps hydronephrosis.

---

[1] Quoted by Fagge, Practice of Medicine, vol. ii. p. 521.

[2] Reynolds's System of Medicine, loc. cit.

[3] Clinical Aspects of Movable Kidney, Lancet, January 11, 1890, p. 66 *et seq.*

All the painful symptoms are brought on and aggravated by exertion, and many patients are unable to walk or ride with any degree of comfort. Constipation alternates with diarrhœa, and the bowels are frequently distended with gas. The stools contain mucus, and there is, indeed, every evidence of gastric and intestinal catarrh. Movable kidney, I am sure, is very intimately associated with vascular disorders relating to the tone of the arteries. In these patients there is always marked abdominal pulsation, and one should be on the alert not to confound the condition with aneurism.

Diagnosis.—The symptoms and features just enumerated should prompt us always to bear this deformity in mind. Other evidences are discovered by careful physical examination of the patient. Absence of the kidney from its normal site causes a slight hollowing of the lumbar region, and percussion may elicit a slightly tympanitic note where naturally it should be dull. When the patient stands, the kidney, according to the degree of mobility and the thinness of the abdominal walls, may be felt as a reniform tumor somewhere in the abdominal cavity, generally just below the ribs. But my experience coincides with that of Drummond, that the simplest and surest way in which to detect a movable kidney is for the patient to lie down with the abdomen uncovered and relaxed. The physician then, standing upon the right side, places his left hand beneath the twelfth rib, on the patient's back, while the right opposes it by pressing down upon the side and front of the abdomen, beneath the arch of the ribs. Then ask the patient to take a full breath, and, as she does so, gently relax your pressure so as to allow a possible kidney to slip downward between your two hands, and, as expiration takes place, you will almost certainly detect the movable organ riding up and down with the movements of respiration. The other side can be similarly examined.

Treatment.—The treatment of movable kidney is either palliative or radical. The first consists principally in attention to the dyspeptic symptoms and general health. Many patients are relieved by bandages and pads by which they succeed in replacing, in a measure at least, the displaced organ. When violent pain or bloody urine makes its appearance, the recumbent posture must be assumed and maintained until these symptoms pass off. The radical treatment consists in surgical interference with a view to establishing permanent replacement by means of sutures or adhesive inflammation.

ALBUMINURIA IN CHILDREN.

BY JAMES TYSON, M.D.

ALBUMINURIA in children may be produced by the following causes: I. Bright's disease. II. Admixture of pus due to suppuration in any part of the genito-urinary tract. III. Hæmaturia and hæmoglobinuria. IV. Chyluria. V. In very rare cases albuminuria may be caused by pressure on the renal veins by tumors or perinephritic inflammation and abscess. VI. Albuminuria may be without apparent cause, when it is called functional albuminuria, or, in children, in consequence of the fact that it is most frequent between the ages of nine and eighteen, the albuminuria of adolescence.

I. BRIGHT'S DISEASE.

This common cause of albuminuria is considered under its appropriate heading in the article by Dr. Goodhart.

II. SUPPURATION.

Pus from the urethra is a very rare source of albuminuria in children. With adolescence in boys comes the possibility of gonorrhœa, while purulent inflammation from mechanical and chemical causes may also occur. In girls at an early age rape is a possible cause of gonorrhœa, as well as inoculation from a parent. Caillé has seen a case of such inoculation in an infant five months old.

Leucorrhœa independent of specific cause is sometimes found in quite young girls, even infants, and comparatively frequently in children three to seven years old and older. The cause in these cases is not always easily ascertained, but the condition is generally observed in young girls who are anæmic and have pale, soft skins,—who are, in a word, scrofulous. The indications of treatment in such cases are to build up the general health of the little patient by the use of nutritive food, hygiene, especially bathing, cod-liver oil, and chalybeates and arsenic. These may be aided by the use of astringent washes, which, as a rule, should be of the simplest character.

After the urethra in the male and the vulvo-vagina in the female, the next source of albumin from this cause is the bladder. Inflammation of the bladder from other causes than stone is not very infrequent in young children, and especially in young girls; but the most frequent cause of such inflammation is stone in the bladder. Inflammation of the bladder by these causes is recognized by symptoms detailed in their appropriate place. But no case of this kind should be decided without the sounding of the bladder, and in the case of the female the urethra should be dilated by Simon's dilators and the bladder explored by the finger. This exploration should be practised much more frequently than it is at the present day.

Ascending the urinary tract, the kidney and its pelvis become the next seat of the source of pus. When they are associated in the inflammatory process, the term pyonephritis is applied. This association commonly exists, and, indeed, it is not often easy to differentiate the two processes when they occur separately, and to be able to say that the inflammation is confined to one or the other. The causes of such inflammation are obstruction anywhere in the urinary tract from its beginning at the end of the urethra up to the pelvis itself, stone in the kidney, tuberculosis of the kidney, and perinephritic abscess invading the kidney from without. Frequently the inflammation is an ascending one, starting from the bladder. Malignant diseases of the kidney, including sarcoma and carcinoma, are also rare causes of pus in the urine. Pyonephrosis is the term applied to a collection of pus in the kidney the result of pyonephritis, by whatever cause produced. Calculous pyonephrosis is due to impacted stone, probably its most frequent cause in children. Tuberculous or scrofulous pyonephrosis is due to tubercular infiltration commencing in the renal papillæ and extending thence in both directions, into the kidney and downward into the pelvis and ureter. The new formation rapidly undergoes fatty metamorphosis and caseation accompanied by suppuration. These will all be described under their appropriate headings, as well as the various forms of tumor which affect the kidney, although these latter are rarely attended with suppuration. They may also cause small albuminuria by pressure upon the renal veins.

It is scarcely in my province to consider the means of determining the exact source of the pus in a given specimen of purulent urine, but I will merely mention, in passing, the case of an adult male extending over four years, during the last three of which he was under my own care, where from the beginning frequent micturition was a most annoying symptom and regarded as evidence of bladder-involvement, and where the autopsy revealed a tuberculous kidney, but a bladder perfectly smooth and free from tubercular disease or inflammation from any cause; also a second case treated for months as a bladder-case by a distinguished surgeon because of an irritable bladder, where subsequently a successful nephro-lithotomy relieved all the symptoms.

III. HÆMATURIA AND HÆMOGLOBINURIA.

Hæmaturia as a cause of albuminuria may be recognized by the naked eye when the blood is sufficiently abundant, or by the microscopic recognition of the red blood-disks in doubtful cases. Hæmaturia occurs in acute nephritis, where the amount of blood is usually small, giving rise only to the well-known smoky hue in acid urine or a brighter tint in alkaline urine. In either event it is best to decide the question by the use of the microscope. In chronic nephritis there is sometimes very trifling hæmaturia. Hæmaturia is frequently the result of injury to the kidney,—traumatic hæmaturia. It occurs also as a result of gravel or stone in the kidney. It is one of the commonest symptoms in tubercular disease of the kidney, especially when the organ begins to break down, although it is not confined to this stage and small amounts of blood may occur in various stages of tuberculosis. Carcinoma and sarcoma are sometimes associated with hæmaturia. Stone impacted anywhere in the ureter between the pelvis and the bladder or contained in the bladder itself may be a cause of hæmaturia. Injuries to the bladder may, of course, cause hæmaturia. Morbid growths in the bladders of children are exceedingly rare, and are therefore very unlikely causes of hæmaturia, but when albuminuria is thus caused it is a true hæmaturia. Cystitis from any cause may be so severe as to be attended by hemorrhage. Among the causes of hæmaturia in children producing albuminuria must not be forgotten the malarial poison, although this form is much more rare in children than in adults. A very interesting case of this form of hæmaturia, closely simulating stone in the bladder, in a boy of seven, is reported by Dr. Mollof, of Sophia, Bulgaria.[1]

Purpura and that singular constitutional tendency to bleed known as hæmophilia must be included among the causes of hæmaturia. The latter is often hereditary.

The question of the source of blood in urine is a very important one preliminary to treatment. The only infallible sign that blood in the urine comes from the kidney is the presence of blood-casts,—casts of the uriniferous tubules composed of coagulated blood or of fibrin to which blood-disks are adherent; or the long worm-like moulds of the ureter which are occasionally discharged where the hemorrhage is free, sometimes with extreme colicky pain. With the latter exception, the blood from the kidney is more apt to be intimately admixed with the urine and is less commonly passed in clots, while clots are comparatively common when the hemorrhage is from the bladder. Here also, however, quantity has much to do with the state of the blood: if the quantity be small there are not likely to be clots, even with hemorrhage into the bladder. The possible admixture with urine of menstrual blood has only to be mentioned in passing.

Hæmoglobinuria differs from hæmaturia in the absence of corpuscles, while the coloring-matter resulting from their disintegration contributes the usual red color of blood to the urine. Where there is any doubt as to whether this coloring-matter is hæmoglobin, chemical tests must, of course, be used, as there is no corpuscle present to recognize with the microscope.

---

[1] Bulgarian bi-weekly Meditzinskï-Pregléi, Nos. 1 and 2, 1889; also Provincial Medical Journal, June 1, 1889.

The simplest test is Heller's, performed by heating the urine in a test-tube with sodic or potassic hydrate. The hæmatin is precipitated with the phosphates, giving to the latter a very characteristic blood-red color. Or the spectroscope may be used, or Teichmann's hæmin crystals may be made.[1]

The term hæmoglobinuria should be restricted to those cases of hæmoglobinuria in which the hæmoglobin comes directly from the blood, for it is to be remembered that in certain cases of apparent hæmoglobinuria the red blood-corpuscles undergo destruction very soon after the urine has been passed, and, if microscopic examination were made at the moment of passing, blood-disks would be found present. Ammoniacal alkaline urine quickly dissolves red blood-disks. The most common cause of hæmoglobinuria is malaria. It must be admitted, however, that both hæmaturia and hæmoglobinuria sometimes occur without discoverable cause, when they are called "idiopathic." Hæmoglobinuria has been experimentally produced by the introduction of poisonous substances into the blood, and it is presumable that whatever agent causes the condition enters the blood and dissolves the corpuscles, either in the vessels or at the moment the blood is discharged from them.

Treatment.—The treatment of hæmaturia and of hæmoglobinuria is identical. In this connection will be considered only the treatment of malarial hæmaturia and hæmoglobinuria and so-called idiopathic hæmaturia and hæmoglobinuria. The remedy *par excellence* for malarial hæmaturia and hæmoglobinuria is quinine, which is given in appropriate anti-malarial doses, although, in consequence of the comparative harmlessness of the drug, and, especially in southern climates, the dangerous character of the disease, full doses should be given at once. It is to be remembered, too, that children bear large doses of quinine with immunity. If the hæmaturia and the hæmoglobinuria are paroxysmal, the full quantity should be given, so as to anticipate sufficiently the expected onset. As determined by the age, ten, fifteen, or twenty grains may be thus given, appropriately divided. Where, however, the hæmaturia is continuous, as it often is, even when malaria is its cause, the quinine may be administered in doses of from one to three grains every three hours, according to the age of the child, until the hæmaturia ceases or there is reason to believe that the remedy is ineffectual. If quinine alone is insufficient, it should be combined with other treatment of malaria, especially arsenic and iron, the latter co-operating as an astringent. Turpentine has been strongly recommended by some of the writers in the southern part of the United States. Cases which do not yield to the above treatment may be regarded as suffering from idiopatic hæmaturia and hæmoglobinuria. By far the best remedies for these are the natural mineral waters, as those of Rockbridge Alum Springs, the Bath Alum Springs, or the Wallawhatoola Alum Springs,—all in Virginia, U.S.A. I have seen almost magical results from the use of these waters in cases otherwise intractable. Other astringents may also be used, as gallic acid in five- to ten-grain doses four times a day, or persulphate of iron in one-eighth- to half-grain doses. Ergot may also be used for its action on the muscular coat of the arteries. By far the best preparation is the fluid extract, in doses of from five minims to half a fluidrachm, according to age.

---

[1] Filter out the earthy phosphates as above precipitated, place a small portion on a glass slide, dry carefully, and thoroughly mix with the dried phosphate a minute granule of common salt. The excess of salt is then removed, the mixture covered with a thin glass cover, a hair interposed, and a drop or two of glacial acetic acid allowed to pass under. The slide is then carefully warmed until bubbles begin to make their appearance. After cooling, if blood-coloring matter is present, prismatic hæmin crystals are easily recognizable with a power of three hundred diameters.

IV. CHYLURIA.

This term is applied to that condition of the urine in which the constituents of chyle are present. It can only occur as a result of leakage of chyle from a ruptured lymph-vessel into the urinary tract, most likely into the bladder or pelvis of the kidney. Such rupture is the result of obstruction in one or more of the branches of the thoracic duct. One of the best recognized causes of such obstruction is the filaria Bancrofti or its embryo;[1] but all cases of chyluria are not by any means due to the filaria. The term *parasitic* is applied to such chyluria, while the term *non-parasitic* is applied to those cases where the obstruction is due to some other cause. The larval filaria is frequently found in the blood. In chyluria there is found, in addition to albumin, the molecular base of the chyle, which gives the most striking physical feature to the urine, its milkiness. According to the quantity of this present the urine exhibits every degree of diminished transparency from a slight turbidity to a total opacity. If the fat is abundant it rises on the surface of the urine like cream, and it may be dissolved out by ether. Considerable blood is often present, imparting a reddish tinge to the chylous urine. The effects of chyluria may be either none at all, or a gradual loss of strength of the patient, proportionate to the amount of chyle lost.

Treatment.—The evident indication for *treatment* for chyluria is rest in bed. It frequently happens that chyluria disappears the moment the patient is placed in bed. Beyond this no effective treatment is known. The condition is of itself often intermittent. Various devices have been at different times suggested for producing pressure upon the chyle-vessels, and thus closing the leaking orifices, but it is exceedingly doubtful whether this treatment is of any avail. Scheube suggests the use of picronitrate of potassium in doses of from three to ten grains, in pills or capsules, three or four times a day,—on what principle I am unable to say.

---

[1] The adult filaria, or *filaria Bancrofti*, is a thread-worm three or four inches long, rarely found in man. The writer has seen a beautiful living specimen floating in the anterior chamber of the eye of the horse. It will be noted that it is of considerable size and can easily obstruct the vessels. The embryo, on the other hand, often, but not always, found in great numbers in the blood, especially at night, and occasionally in the urine, is a microscopic creature from one-hundredth to one-eightieth of an inch long, and about one-three-thousandth of an inch in diameter.

V. MORBID GROWTHS.

Albuminuria as the result of pressure by morbid growths requires no further mention. In addition to sarcoma, carcinoma, rhabdomyoma, and fibroma, as forms of morbid growth thus acting, should be mentioned hydatid cysts.

VI. FUNCTIONAL ALBUMINURIA, OR ALBUMINURIA OF ADOLESCENCE.

By far the most interesting form of albuminuria, next to that of Bright's disease, is the so-called albuminuria of adolescence. By this is meant an albuminuria renal in origin, further characterized by the absence of casts and of all other signs of Bright's disease, or indeed of any disease, as its subject is in apparently perfect health. It is much more common in boys than in girls. The amount of albumin in these cases varies greatly. Sometimes it is quite large, amounting to half the bulk of urine tested, but more frequently it is moderate in amount or very small. It is also greatly influenced by circumstances. Thus, it is apt to be increased by the ingestion of food, and especially by fatigue, and it is almost always entirely absent on rising in the morning, returning with the resumption of muscular activity, whether food is taken or not. The most important injunction in the recognition of this form of albuminuria is a careful and exhaustive examination of the urine for casts, for should one fail to find them when they are actually present a most serious error in diagnosis results. All attempts to explain this form of albuminuria must be based on speculation. Careful thought, however, leads to the suggestion that it may not be so much the result of derangement of the circulation of the kidney as a defect in the composition of the albumin in the blood due to mal-assimilation, in consequence of which defect it transudes through the vessel-walls. In structural change, on the other hand, there is a hinderance to the movement of the blood through the kidney, and from this cause a transudation of the albumin takes place. Up to the present time, however, no chemical researches have been able to discover a difference in the composition of the albumin excreted under these circumstances. Functional albuminuria is by no means confined to childhood.

Treatment.—Having once recognized this form of albuminuria in a child, what shall be its management? First and foremost is the diet, and a very nice question it is to settle. A growing child should not be too much restricted in the quantity of food, but care should be taken that it be of the simplest character and most easily digested. Milk is conspicuously appropriate: it is easily digested, and should be freely allowed. Nor should nitrogenous foods be excluded from the diet of such a child. At the same time care should be exercised not to permit the too free use of meat and of other albuminous foods, such as eggs. Too free eating should also be avoided at the evening meal, which should be of a simple character. For a child "bread and milk" is a typically suitable evening meal. Of equal importance is the regulation of the amount of muscular exercise. Over-exertion and extreme fatigue should be avoided, and competing in athletic sports should be prohibited, because here not only is the exertion excessive but there is also no power to regulate it. Young girls during the establishment of menstruation should be put to bed. On the other hand, out-door life is important for both sexes. It is to be remembered that boys and girls with true functional albuminuria are not ill, but are in a state which may easily be converted into illness, and, while they require to be watched, they are not to be treated as invalids. Medicines are, therefore, scarcely needed except to meet symptoms. Anæmia requires to be treated with iron in *small* doses,—only such as can be assimilated: all over this is harmful, as it is not absorbed, but, remaining in the alimentary canal, acts as an astringent, constipates, and otherwise deranges digestion. It is impossible to direct definite doses, because they must vary with the age of the child, but even with girls and boys of eighteen a fluidrachm of the well-known Basham's mixture of acetate of iron is quite enough. It should further be freely diluted, as its absorption is thus favored and the astringent effect diminished. As a rule, too, the vegetable salts of iron are by far the best, because they are more easily assimilated. Such are the citrate, tartrate, and malate of iron, in doses of from half a grain or less to two grains. In girls at all disposed to chlorosis, arsenic is a valuable addition, in the shape of Fowler's solution or arsenious acid. The well-known Blaud's pills of carbonate of iron are useful, but I doubt whether they are any more efficient than the freshly-made pills of the same substance.

ACUTE AND CHRONIC BRIGHT'S DISEASE.

By JAMES F. GOODHART, M.D., F.R.C.P.

The term Bright's disease has now for so long a period occupied a recognized position that, although it is an interesting subject of study to trace out from a utilitarian point of view the development of this as of every other progressive advance in medicine, there is little need to occupy time here either in a history or in a definition of the malady.

Nevertheless, as regards the latter I will say thus much, that, excepting abscess, which will not concern us, any inflammation that attacks the secreting structure of the kidney, whether that inflammation be catarrhal or interstitial, partial or general, is essentially Bright's disease more or less, and any less comprehensive definition leads not to perspicuity but to perplexity, for it is some such wide embrace as this alone that admits of any attempt to explain the many varieties of symptoms and groups of such which severally present themselves. Upon this point, therefore, I would venture to insist: it is of cardinal importance to the subject as presented in this article.

Plan.—In any article on Bright's disease there are many interesting questions that are of the essence of the subject which invite attention and discussion. Such, for instance, are the cause of the anasarca and of its presence or absence in particular cases, the problems that centre round arterial tension, and so on. But I have throughout kept rigidly before me that childhood only is my sphere on the present occasion, and, in consequence, only such points in the general pathology of nephritis are touched as are within the limits of this restriction, or as seem to be in any measure elucidated by their occurrence under the particular conditions. For the same reason I have avoided any general description of nephritis.

There are many methods of handling the subject. Some treat of it clinically, and describe an acute, a subacute, and a chronic form,—all more or less associated with dropsy; and the granular kidney where dropsy is absent. Others subdivide the subject pathologically according to the supposed change in the kidney, when we have a tubal, a glomerular, and an interstitial nephritis. No one of these commends itself entirely to my judgment, because, as I shall venture to maintain, the several subdivisions frequently overlap one another, and, after much consideration, I have decided to make a very general division and to treat of only two groups: 1, acute Bright's disease; 2, chronic Bright's disease.

Under the first heading will be included not only the cases of definite and stormy onset and moderate duration, but also all those chronic processes that are known to come about in some cases by such means, although it is possible that they sometimes start in more leisurely manner, and certainly by their prolonged course deserve the name of chronic. This group will therefore include the acute, subacute, and chronic desquamative, tubal, or parenchymatous nephritis of the several authorities, and the obvious justification for classing them all together thus is that it is impossible to give any specific differences that will suffice to distinguish them. There is no dividing line, the disease is the same for all, whether acute or chronic, and the symptoms of any one are more or less those of the others.

Chronic Bright's disease will be practically conterminous with the contracted or granular kidney. There is indeed another condition which is chronic from the commencement,—viz., the chronic parenchymatous nephritis that is set going by lardaceous disease; but its symptoms are those of the late stage of parenchymatous nephritis, and to treat of it separately would only be to repeat myself.

If at first sight the arrangement here adopted seems to be wanting in precision, I think it will be found to work out satisfactorily, and as nearly in accord with practical usage as can be hoped for.

ACUTE BRIGHT'S DISEASE.

Synonymes.—Tubal nephritis, Parenchymatous nephritis.

Etiology.—In adults the great proportion of cases can be traced to exposure to wet or cold or both. Almost all other causes are obscure in origin, but in some it arises after scarlatina or other blood-poison, be it diphtheria, typhoid fever, erysipelas, or acute rheumatism; in others the patient has been for long markedly anæmic. Sometimes it is associated with drinking habits. Sometimes, started by lardaceous disease, it soon assumes a dominant position and the original mischief is completely masked. But in children it has often been the subject of remark that it is but seldom that any exposure can be traced, and for the most part scarlatina is held to be its common cause. Ralfe states that two-thirds of all the cases of acute nephritis under sixteen years are due to this exanthem; Henoch, that one can boldly assert that, with the exception of an extremely small number of cases, diffuse nephritis in infants is of scarlatinal nature;[1] and Dr. Dickinson, that of fifty-four fatal cases the disease was traced to wet or cold in only four. At the same time let it be remarked that a chill is not an easy thing to trace in childhood, and, now that we are becoming familiar with the fact that nephritis is more common in very young children than used to be supposed, it is yet possible that exposure may play a more prominent part as a factor in its production than these statements would lead one to suppose. Of other causes fertile in adult life in initiating the more chronic form of the disease, and which ought not to be omitted from some share of responsibility even in childhood, are phthisis and lardaceous disease. Neither is of any great numerical import; nevertheless, it may be as well to insist that lardaceous disease, even in slight degree, is a provocative of chronic parenchymatous nephritis, and even of more insidious changes such as may ultimately bring about a granular kidney.

[1] Vorlesungen über Kinderkrankheiten, 1881, p. 510.

Pathological Anatomy.—If we refer to the many authorities who have written on this part of our subject, it must still be held that there is weighty opinion in favor of two contentions: there are those who still hold that the disease is of epithelial origin; others, that it is essentially an acute interstitial change with consecutive epithelial disturbance and proliferation. Barthez and Sanné, after citing these two views, continue, "Others, in the desire to reconcile these opposite opinions, have conceived the existence of a mixed or diffuse nephritis." But, in my opinion, the assertion that the disease is a complex state of tubal and interstitial change rests upon solid ground; for it is based, first of all, upon a number of recorded facts, and, secondly, upon the *a priori* argument that it is exceedingly unlikely that in any solid and closely-packed organ like the kidney, and which wants the excuse of separate functions such as the liver may supply an example of, or the openness of texture and thus the greater or less independence of the elements of its structure, as is seen in the lung,—I say it seems to me highly improbable that there should be two specifically distinct forms of inflammation or structural change. Physiology and anatomy alike make it more than probable that unity runs through all forms of nephritis; that it is, in fact, impossible for any disease of the tubes to exist any length of time except more or less interstitial disease accompanies it; and that it is equally impossible for any interstitial disease to exist independently and not to entail a tubal disturbance or desquamation. To this it will be at once objected that a dogmatic statement of this kind flies in the face of obvious every-day fact. Take a typical case of the large white kidney—and what more common?—and contrast it with the granular kidney, also too familiar to us all, and the two are so unlike that any *a priori* argument such as I have ventured to employ is of no value, and particularly so when the dissimilarities are in accord with the minute investigations of many most reliable observers. And I admit the cogency of the objection unless it can be satisfactorily disposed of. Let us see whether this is so. It is no mere truism to say that inflammation wherever we study the process is hardly in any two cases alike, because it is this very feature of inconstancy—whether this be due to the disease or to the personality of the individual, who shall say?—that is forever demanding attention, puzzling our diagnosis, and too often eluding our forecast. And to no other feature than this is it necessary to look for an explanation, and I think a satisfactory one, of the various morbid appearances met with in nephritis. From reasoning based upon the premises thus supplied, it is not difficult to construct a synthetic scheme of the morbid changes of renal inflammation, as follows:

The most acute form of inflammation, from what is known of the process in all tissues, must necessarily be mainly an intense arterial flux. It is impossible to get fire without fuel, and no epithelial proliferation can take place without preceding hyperæmia of some kind, and it is possible to conceive of a vascular condition of this kind so intense as will practically put a stop to further changes by the extreme disturbance of the circulation thereby induced. In the case of the kidney extreme congestion of the Malpighian tufts—a common occurrence—is the initial disturbance, and this would be followed in a smaller number of cases by exudation and damage to the structure of the tufts themselves. In this description any one can see the picture of the essentials of the so-called glomerular nephritis.[1]

In the same way suppose the circulatory stasis to be less severe but its stress sufficiently maintained, and it would be strange if there did not follow an outwandering of corpuscles and other disturbances of the walls of the vessels and of the surrounding parts such as would readily correspond to the description of an acute interstitial nephritis. Far and away behind these in the matter of intensity would come such a flux as would allow of epithelial desquamation, and in cases where this morbid change was excessive one might even hazard the surmise that the attack was chronic. One might even go further, and say that in all such cases as have been really acute one would expect to find such a blending of circulatory—that is, interstitial—changes with the epithelial—or tubal—that the latter should be, after all, not so very prominent.

Most chronic of all would necessarily and obviously be those contracting forms of disease that have received the name of "granular kidney."

This description—subject to the qualification already insisted upon, that absolutely pure cases are the exception—will account for a considerable amount of variation in the appearance of the kidneys, as also for intermediate cases as regards the symptoms exhibited.

This scheme, be it observed, is altogether beside the knowledge obtained from the clinical and post-mortem study of the disease itself; it is purely hypothetical, and we must now inquire how it works out in practice.

Now, the one feature of the morbid anatomy of Bright's disease as seen in childhood that has impressed itself upon my mental vision is this: that the naked-eye appearances of the kidney are not at all in proportion to the severity of the symptoms; and in my own experience a typical large white kidney is but seldom found. Many a time, with all the symptoms of that disease—the pallor, the dropsy, the scanty, smoky urine, with much albumin in it—the kidney by a casual observer might have been passed as healthy. To careful scrutiny there is no doubt about the disease. There is the patchy dilatation of the surface capillaries, and a generally-distributed but subdued fawn-colored speckling. Still, the general aspect is by no means striking: the kidneys, perhaps, are not unduly large, their color might easily pass for that of a pale or what is often called a fatty kidney (a familiar term in the post-mortem room, and carrying no suggestion of parenchymatous nephritis), and their section shows none of that extreme contrast between the lividity of the medullary and the pallor of the cortical parts. Passing on to the minute examination of such organs, I have been further struck with the want of uniformity that is to be found in the histological changes: kidneys of very similar external appearance will show in one case much glomerular change, in another much tubal, in another more diapedesis, in another very little of anything except intense congestion of the vessels behind the tufts. The most recent histological investigations are much in accord with this. Barthez and Sanné, as the result of their most recent summary, state that in all cases of parenchymatous nephritis, whether consequent on scarlatina or on some other malady, the initial departure is a glomerular and vascular one.[1] So much is this want of uniformity a feature of nephritis in childhood—it is by no means wanting in adult life also[2]—that when asked—as, necessarily, often happens—what kind of kidney is to be predicted in a particular case, although it is easy to say in the rough that such and such minute changes will be found, I hesitate always to say what the coarse appearances will be.

---

[1] For a very similar view see H. Ashby, Med. Chronicle, vol. iii. pp. 187–189.

I take it that this statement of the case is equivalent to saying that the average of disease in childhood is *acute*, whereas in adults the average is *chronic*. There can be no doubt of this: that the prognosis for parenchymatous nephritis as regards complete recovery is largely a question of *age*. In childhood it is mostly good; in young adults, also, often good; but as years go on it certainly becomes less and less so, and in a large proportion of hospital cases (mostly of middle age) admitted for albuminuria and dropsy, although the immediate risk may not be great, and many are much relieved by treatment, the albuminuria persists, and the ultimate issue, even if long delayed, is unfavorable.

But in this I am anticipating. It is, however, necessary to say so much, because the different behavior of the disease at the two epochs forms part of the argument upon which I base the contention that there are other phases of acute nephritis more acute or intense than the so-called acute tubal nephritis, and that this last is not *par excellence* the disease of childhood, but that, on the contrary, there are strong grounds for supposing that in many cases it is the result of insidious chronic disease.

[2] See a paper by the author, Guy's Hosp. Rep., Series III., vol. xxvii. p. 135.

This view will, I think, receive still further support from the clinical history of the disease.

Symptoms.—These will be best brought home to the mind of the reader if they are presented not separately, but as they are moulded into form by the disease. We are all familiar with the symptoms of acute Bright's disease as a mere matter of enumeration,—the pyrexia (I think, occasional only, and usually of moderate intensity), the pallor, the vomiting, the convulsions sometimes; then the dropsy, the cough, the oppressed breathing, the pulse that intermits now and again, the scanty urine, its blood, its smokiness, and its large percentage of albumin. But what we want to know more especially is, how do the individual elements adjust themselves, with what body do they come?

The common history is this: the child becomes dropsical and pale: in consequence of these two symptoms, perhaps only of the swelling that has been noticed in the face, the doctor is summoned; and he finds that the urine is scanty, perhaps even this not remarkable, but the color is dingy, or, as it is called, smoky, it contains a large proportion of albumin, and under the microscope red blood-corpuscles are found, a number of leucocyte-like bodies (probably the nuclei of the renal epithelium), other cells in less proportion, and abundant hyaline casts, of a size denoting that they come from the cortical part of the gland. If inquiry be made, a history of some slight preceding malaise may be elicited, of any length from four or five days to a month, perhaps of some moderate pyrexia. This is about all that can be said of the onset of the average run of cases, but there is a good deal of latitude in all directions. Thus, as regards cerebral symptoms, the disease is sometimes ushered in by convulsions, or there may be early obstinate vomiting, but these are less common, and headache is not a feature of the nephritis of childhood,—or perhaps, to speak more guardedly, it is seldom complained of as such.

If the case does well, after more or less time has elapsed the albumin perhaps begins to vary and on the whole to lessen gradually in quantity, the dropsy decreases and then goes, the urine becomes more copious, its specific gravity improves, perhaps lithates appear, and ultimately the child improves in flesh and color. If, on the other hand, the case progresses downward, the albumin remains in quantity for a long time and the amount of urine is scanty; after a time the diuresis becomes more free, and often much of the dropsy goes, but the child remains pale and emaciated; the albumin persists, and death ensues by one of several complications after perhaps many months. With this history of the common case the separate symptoms may be considered more in detail.

Convulsions at the onset, or indeed at any time, are usually associated with and preceded by a markedly scanty urine or even by temporary suppression. They are likely to cease in the course of a few hours under the influence of treatment and of the establishment of a more free secretion of urine.

Vomiting, if severe, is more likely to be associated with unusual pallor, a [illegible] [illegible], restlessness, cough, a diffuse bronchitis of the larger tubes, or that the chest is pervaded, sometimes quite rapidly, with râles of all kinds, the so-called œdema of the lung. This is not always the case: vomiting is sometimes severe when the child is still in a fairly good condition, and it does not then appear to add to the gravity of the case [illegible]. The ejecta are sometimes bilious or greenish, sometimes watery, sometimes mere mucus.

Pyrexia is sometimes high (103–104° F.), but it is seldom more than 101°, often [illegible] and altogether overlooked, and in any case it is seldom of any duration. The temperature is often subnormal. Barr states that post-scarlatinal nephritis always sets in with more or less febrile disturbance.[1] I have occasionally noticed the accession of a sharp febrile attack of perhaps two or three days or less, in the course of an acute nephritis. It has speedily subsided, nor has it been associated with any relapse in other ways, but when it has occurred, and this in intensity, the pulse has become for the time a characteristically dicrotic one. In the primary nephritis of infancy, too, a pyrexia of some degree and duration is perhaps not uncommon: Emmett Holt has given charts of several such.[2]

The *urine* almost always contains a large quantity of albumin at the onset, unless we have regard to a special and rare group of cases, to be mentioned presently, in which the anasarca is extreme and the albumin absent. The quantity passed in the twenty-four hours varies considerably. Ralfe states that the general average is in his experience from 6 grammes to 13.5 grammes in the twenty-four hours, but Dickinson, according to the same authority, has recorded cases where the amount has been as much as 21.9 and 32.5 grammes.[3] It may vary in quantity, and sometimes much so, from day to day. I could give several charts where in the course of a long attack the estimated quantity jumped about from day to day, and sometimes temporarily disappeared altogether. In other respects than the albumin the urine may also vary much. It is usually scanty at the onset, and it may long remain so, or it may quickly become copious; it may be fully charged with blood, when it is of the color of claret,—a state of things that is in my experience decidedly uncommon. More commonly it is of a definite blood-tint (like raw-beef juice) or only smoky. If the case is of any duration I have often noticed blood to appear and reappear in the course of the illness without any other change in the symptoms, and without, so far as I know, adding anything to alter the prognosis.

Of *polyuria* and *thirst* I shall speak presently. They are not common, but may occur in very chronic cases.

The dropsy is usually a persistent symptom, but not necessarily so: it may be that with rest and treatment it quickly disappears, its disappearance corresponding with considerable diuresis and generally with a diminution of the amount of albumin in the urine. It is important that this association of signs be attended to, for there *is* a disappearance of dropsy unassociated with lessening of the albumin, which is prone to indicate a very chronic malady and one that is little likely to end in recovery. Moreover, dropsy is not by any means always present: cases sometimes run their course from first to last without any, and this may be so in such as end fatally as well as in those that do well. It sometimes happens, too, that after it has disappeared and the albumin also, a slight relapse in this respect will take place and the child again become puffy about the face or the ankles. This is, of course, quite a common thing in the chronic cases and with the albumin persistent.

Heart and Arteries.—Another very common departure from health is more or less disturbance of the heart's action and of the pulse. I have already described the latter as intermittent, but perhaps it less seldom misses a pulsation at the wrist than that an occasional beat falls short of its proper volume and power; while, if listening to the heart-sounds, perhaps once in eight or ten beats there is a one-beat stagger or shuffle. This symptom is, I think, more conspicuous in adults than in children, and is generally associated with more or less of the well-known pulmonary distress or asthma,—air-hunger, as it has been called,—a symptom of renal disease almost absent in childhood, perhaps because it belongs more to chronic than to acute disease, and chiefly, of course, to the granular form of kidney. The heart is often laboring in its action, its sounds thick, and its impulse displaced outward.

In childhood the pulse of renal disease is usually an accelerated one; it seldom to the finger conveys the idea of hardness or tension so characteristic in adults, and only occasionally have I seen anything of the kind in the sphygmographic tracing.

These points are all of importance, because Friedländer, Silbermann, the writer, and others have found the left ventricle dilated in certain cases of death from acute nephritis, and I have contended for this condition coming on somewhat rapidly and causing death suddenly, and somewhat unexpectedly if we are not prepared for such an occurrence. It has been argued with much probability that the dilatation of the ventricle is the result of increase of tension in the systemic system, the heart, becoming fatigued by the stress of work, acting irregularly, and then dilating. But Henoch has combated this suggestion, and reverts to the theory of uræmia or of some cause at present unknown. His objections are three:

1st. That evidence of arterial tension often fails. This I at once admit, but it would be strange if it did not do so, for, inasmuch as increase of tension must be due in part to the requisite vigor of the cardiac muscle, when this fails and the ventricle dilates rapidly so will the evidence of tension disappear. It is to this very fact that I attribute the *common* failure of this evidence in children, and I say that rapid dilatation of the heart is a special risk in early life.

2d. The heart is said to be found sometimes dilated at the autopsy when the pulse has been quite regular all through. This, again, must, I think, be admitted, and may even be regarded as a difficulty; but, at the same time, we know as a fact that this is not uncommon in adult life, in chronic disease, and in conditions of obviously increased tension; and one can therefore only suppose—what is not, indeed, unlikely—that the heart may slowly dilate under the influence of the tension while the muscle still is enabled to fulfil its functions adequately.

3d. It is said that, inasmuch as most cases recover, it is necessary to suppose a frequent recovery from dilatation of the ventricle, and that this appears but little likely. On the contrary, I am convinced of the reality of the frequency of recovery from dilatations of this sort. There is many a case of renal disease in which under the influence of disease the impulse goes outward and the heart-sounds are laboring and unnatural, in which the natural conditions are restored as the malady subsides. The cases of anæmia could be numbered by the score in which the same physical signs, coupled with subjective symptoms of disturbed cardiac action, all combine to indicate dilatation of the ventricle, and all completely subside under the influence of rest and the administration of iron; and I take it that one of the most vital points in medicine to insist upon is this power of the heart to recover from temporary dilatation.

Skin.—In adults, as is well known, the skin is usually dry and perspiration is difficult to provoke, but in children this is certainly nothing like so regular, and in many cases even of general anasarca it is either naturally active or at any rate is readily excited to sweating.

Retina.—I have only once or twice seen albuminuric retinitis in childhood, and this in somewhat chronic and fatal cases.

But there are tableaux of symptoms other than this. Thus, a child is taken suddenly, after scarlatina in the particular case that now presents itself to me, with hæmaturia. It is not at any time extreme, and disappears within three or four days, but the urine becomes more and more scanty and ends with complete suppression. Except for this history there is nothing to indicate the malady with which we are dealing. The child lies in bed without a trace of dropsy, and at the end of seven or eight days dies of sheer asthenia. I recall a very similar case in a youth of sixteen or seventeen who could give no cause for his illness. The picture is noteworthy because of the complete absence of the so-called uræmic symptoms, in this corresponding to a class of cases in adults, now well known, chiefly from the writings of Sir William Roberts, due to mechanical arrest of the outflow of urine, in which death also comes by asthenia. I should say that in both the cases above alluded to, the microscopical examination of the kidney revealed an unusual degree of glomerular nephritis and very little else.

And yet another scene floats before me, perhaps more common, in which there is the same absence of dropsy but albuminuria and anæmia are coupled together, yet so little are any other symptoms of renal disease present that one is tempted to ask which is the primary disease. Of the minute changes in the kidney in such cases as these I am less sure. The naked-eye appearances I have already dilated upon as those of pallor, or the fatty kidney. But the minute changes have sometimes been so little pronounced as to give color to the suggestion that some forms of albuminuria are of hæmatogenous origin. Here is a case that illustrates some of the difficulties of this class. A child of eight years was under treatment for headache, drowsiness, and obstinate vomiting. The illness had commenced by convulsions, without pyrexia. The urine, said to have been normal at one examination at the onset, had for several days contained a large quantity of albumin and was pale and watery-looking. Latterly there had been some bleeding from the gums and the face had become puffy, but this was hardly appreciable to a stranger, and there was no trace of dropsy elsewhere. There was excessive anæmia, and the urine was full of albumin. These and the vomiting were the only symptoms, and it seemed possible that the albuminuria might have some obscure cause in the anæmia, or even some other blood-condition, such as diphtheria may supply us with an example of. The child died at the end of six weeks, the vomiting having continued, and intermittent suppression closing the scene. The kidneys were the only organs diseased: they were of natural size. The capsules were adherent; the surface slightly dimpled; in color pale fawn, and mottled. They had all the appearance of extensive parenchymatous nephritis of some weeks' if not months' standing, and by the microscope the excess of fibre between the tubes, the thickening of the vessels, and the wasted tubes, all combined to show the existence of a rather advanced interstitial change.

Then, too, although the *average* of disease in childhood is more or less acute, occasionally it is the very opposite. And parenchymatous nephritis is sometimes a disease of onset so insidious that it cannot be said to own any perceptible or characteristic beginning. In that case an insatiable thirst may herald the disease when it would otherwise be overlooked or pass for something else,—"diabetes insipidus," for example. The two following cases illustrate both these points,—that the disease may be very insidious, and that for the diagnosis of such cases thirst may be the guiding light. This symptom is also mentioned later on as existing in a case of granular kidney.

A boy of six years was brought to me with the following perplexing history. He was brought up by hand on milk and oatmeal; when the bottle was given up he developed an intense thirst, which had never subsided, and for which he would drink as much as a quart of water during the night, and in times past even more than this. In early life he would have an occasional attack of sickness after excitement, but was considered healthy until the age of three years, when he had a sudden and severe attack of fever and vomiting, thought by one medical man to be a cerebral inflammation, by another to be of gastric origin. After his recovery he suffered from bad night-terrors, and ever since has been subject to severe attacks of tetany and periodic attacks of vomiting. His urine had been examined from time to time, and it was always of low specific gravity; it sometimes contained albumin, sometimes not, and never more than one-twenty-second part. He had not had scarlatina nor measles. I found him a wizened-looking child weighing thirty-one and a half pounds, with a dry skin and eczematous patches about the face. The parents evidently had great difficulty about his diet, but there were no indications of any disease, except that the urine had a specific gravity of 1005 and contained a good deal of albumin. There were no casts. There was no trace of dropsy. From that time until his death, about three months later, he was under the close supervision of Dr. Dring, from whom I learned that the albumin sometimes quite disappeared, the polyuria persisting until a short time before death. But the peculiarity of the case was that almost punctually once a month he had a relapse, the tetany reappearing, the urine becoming scanty and so full of albumin as to be nearly solid; the attack would then pass off, the albumin diminishing rapidly down to none, or a trace. He died in one of these attacks, comatose, and in a state of opisthotonus. At the autopsy, at which I was present, both kidneys were small and shrivelled, their capsules adherent, the surfaces pale and speckled with fatty products, the cortex much diminished in thickness, the pelves a little dilated. Their structure was much diseased; a large excess of fibre permeated and spoiled the cortex, and many of the Malpighian tufts were shrunken and in a state of hyaline degeneration. The vessels were thick, but this was not a remarkable feature of the case. The heart was large, flabby, and widely dilated. No disease of the other viscera or of the brain was found. The urine in the bladder was pale, and contained about a sixth of albumin and a few doubtful pieces of fatty casts.

Within a few weeks of the death of this child its cousin was brought because its symptoms resembled those of the other case. The history is as follows. A girl of six and a half years. The parents are healthy people. This is the fifth child of a family of six of whom one died a few weeks old of whooping-cough, and another (the third in the series) of atrophy and "diabetes" at the age of twenty-two months. The mother states this spontaneously, and adds that it both drank and passed large quantities of water, but that the urine never contained any sugar. An attempt was made under medical advice to curtail the fluid imbibed, but the child suffered so much from the thirst that it had to be relinquished.

The present patient was never a strong child, but nothing was noticed specially wrong until weaning. It was at that time that she began to suffer from intense thirst, which has continued ever since. Her sleep is much disturbed because of it. She has taken as much as three pints of water in the night and a similar quantity by day, and she is always wanting to drink. She has bad attacks of sickness at times and intense headache with intolerance of light, and within the last three months she has had an attack of severe cramp in her legs (? tetany).

She is a wizened-looking child, with a dry skin and a patch of distended capillaries on each cheek. Her weight is only twenty-seven and a half pounds. Her tongue is clean, but red. There is no trace of anasarca, nor has there ever been. Her urine is very pale, has a specific gravity of 1004, and contains one-sixth of albumin. There was absolutely no deposit in the urine after long standing, and no casts could be found. The heart and blood-vessels were natural, and the retina was free from changes of any kind.

To these must be added the group of cases of nephritis in infancy in which, apart from the results of examination of the urine,—when, in all probability, casts as well as albumin will be found,—there are no recognizable symptoms. Holt writes,[1] "The symptoms, as a rule, are misleading, and tend to attract our attention to the brain or digestive system rather than to the kidneys." In many of the cases collected by this writer, twenty-three in all, fever is mentioned, the pulse was rapid, the respiration peculiar, and the nervous symptoms prominent. As a good illustration of how difficult the diagnosis of nephritis in childhood may sometimes be, the following case may be quoted.

A little girl of eight years was admitted into the Evelina Hospital under my care on one day, and died the next. Her previous history was that she had always been easily upset by food, and would then be sick and feverish, with abdominal pain, for a few days. One of these attacks, apparently, commenced seven days before her death, when she was quite well. She felt sick, had stomach-ache, and was feverish. She afterwards vomited repeatedly, and when admitted on the sixth day she was in a very alarming condition. She was pale, drowsy, ashy in appearance, with subnormal temperature, cold extremities, and imperceptible pulse. The heart-sounds were rapid and irregular. She passed an ounce of urine soon after admission, of 1030 specific gravity and containing casts and one-tenth albumin. She passed no urine for many hours, and just before her death became convulsed. The heart was large and the left ventricle dilated. The kidneys had the appearance of chronic congestion and felt hard, the capsules perhaps a little adherent. The microscopical changes were not pronounced; the vessels of the cortex were full of blood and in many of the tubes were fibrinous casts.

Course and Duration.—This will depend upon several circumstances. Given an average case of scarlatinal nephritis, the attack usually supervenes in the second or third week. The urine improves in color and in quantity after a few days, and in a fortnight or so the amount of albumin will have considerably decreased. The albumin may continue to diminish, and may disappear in from three to five weeks, or it may linger on, with mild relapses and ultimate cessation, for many weeks, and sometimes for months.

But I am disposed to think that the age of the child enters into the question. I have already said that the nephritis of childhood is more likely to do well than that of adults, and this applies probably without limitation from the one extreme of life to the other. Then, from what I have seen, the nephritis of infancy is likely to run a rapid course, the dropsy to disappear, and the urine to regain a natural state almost in a few weeks. The ground for such an opinion is admittedly not a very extensive one. It may be that the nephritis of infancy is largely unrecognized, and that in this part of its history come the fatal cases to swell the list. Dr. Emmett Holt[1] has published a paper on the primary nephritis of infancy, which rather confirms this view of the case; for, in the first place, the facts therein recorded agree with others of Sée and Ashby, in showing that nephritis may be wholly latent and pass unrecognized unless the urine be examined in all cases of illness; and, secondly, the deaths amounted to eleven out of nineteen. Dr. Holt adds, however, that this mortality must not be supposed to represent the real death-rate from these forms of nephritis, the truth, no doubt, being that the great proportion of the milder cases escape notice altogether. The few cases I have seen in infancy associated with dropsy have done well. I have published one such case.[2]

---

[1] Primary Nephritis of Infancy, Archives of Pediatrics, 1887, p. 114.

Another occasional peculiarity of nephritis in childhood is a somewhat tedious course for many weeks of albuminuria and anasarca, and then a rapid, not to say sudden, disappearance of both, and recovery, when one had almost begun to be despondent. I give a short note of two such cases.

A boy of three and one-half years was admitted to the Evelina Hospital on October 4, 1886. Some four months before his admission he had an attack of fever: he was hot and thirsty, but had no rash out, and about this time it was also noticed that his urine was scanty and dark ale-colored. It had occasionally been of the same color since. Swelling of the legs, etc., had come on gradually since then, and for five weeks before his admission he had been in bed.

He was in a condition of extensive anasarca, no part of the body being free. The impulse of the heart was in the fifth space, just internal to the nipple-line, and the action was rather irregular, there being a half-pause every third or fourth beat. The sounds were flappy and the second reduplicated over the pulmonary area. The urine had a specific gravity of 1010, and contained one-third albumin, with granular and hyaline casts. From October 4 to June 10 he remained much the same, and on the latter date the albumin still measured as much as a sixth after settlement. It had averaged throughout from a third to a sixth, but there had been several temporary drops. To this it must be added that the child was hardly to be called ill for the greater part of the time, although in this matter, too, he varied, being sometimes very poorly for a day or two and then causing some anxiety. Towards the end of February the dropsy began to diminish, and soon all but disappeared. In April the specific gravity of the urine rose from 1010 or 1015 to 1025–1030; it was habitually scanty in quantity, hardly ever being more than seven or eight ounces. On June 10 the albumin was at one-sixth, next day it had gone to one-twenty-fourth, and within four or five days there was none. A trace reappeared afterwards, and this remained on his discharge six weeks later. He was treated almost throughout by the wet pack twice a day. It answered well, and he sweated profusely. A subcutaneous injection of one-twelfth of a grain of pilocarpine was given occasionally; citrate of potassium and digitalis for a time; and after some few weeks iron continuously.

---

[1] Archives of Pediatrics, 1887, vol. iv.

[2] Student's Guide to the Diseases of Children, 3d ed. 1888, p. 425.

The second case was also a boy, aged four and a half years. He had been ill with dropsy only a week, and for the same time the urine had been only a few ounces in the twenty-four hours. He was very short-breathed, with extensive general anasarca; the urine 1026, full of albumin, and containing large numbers of hyaline and finely-granular casts. The heart-sounds were thick and long, and the second accentuated. He was treated by the wet pack and by citrate of potassium in seven-grain doses given every four hours, his diet being restricted to milk and water, jelly, biscuit, and bread and butter. The albumin decreased somewhat under these measures, but it remained in fair quantity for four months, the specific gravity being from 1012 to 1015, and the dropsy disappeared, but the health of the child remained at a very low ebb. At the end of this time the specific gravity of the urine rose suddenly to 1020, and the albumin disappeared altogether within a few days, and he has since then remained well.

It is impossible to reflect upon such a history as is here given, without being struck with the fact that it does not square with any idea of inflammation present to the morbid anatomist, and that it much better accords with the supposition of some circulatory stasis that has been suddenly unlocked, or of some hæmatogenous manner of production of albumin in the urine of which as yet we know nothing. Of course there are many conditions under which albumin, even in quantity, comes and goes. But that it should be present for some weeks and even months, and then suddenly disappear, is not common, although diphtheria may supply some approximation to this requirement. I remember, also, to have once seen something like it in a severe case of typhoid fever, in which the albumin remained in quantity for many days after convalescence, giving rise to some anxiety, and then vanished like a dream. For the rest, one can occasionally trace an acute nephritis, sometimes with dropsy, when it will all disappear, sometimes without it, in which case the albumin, although for a time it diminishes, never disappears, in which, some years after, a granular kidney is found. I have seen one or two such cases. This event appears, however, to be more likely, as I shall presently relate, when there has been no dropsy, or when the dropsy has been but slight and transient. It is certainly not common in childhood to find, as in adults, the anasarca remaining for some time and then disappearing while the albumin remains, a mixed or, as some would say, a contracted white kidney being found after death.

In children, as in adults, the dropsy may be very persistent and the patient die of a large white kidney after many weeks or months. Cases of this sort must be present to the minds of all my readers. Several of the kind are given by Dickinson,[1] and others may be found in the admirable abstract of medical and surgical cases emanating from the General Hospital for Sick Children at Pendlebury. As I have already said, they have not been the common cases in my experience.

Diagnosis.—When all the symptoms are present by which the disease is known in adult life, no difficulty can present itself that requires mention. The points to bear in mind are that most of them may be absent, and that the younger the child the more likely is this to be the case. Not only so, but other symptoms may exist that seem to point in quite other directions. One child may suffer from sharp fever; another may be drowsy or convulsed, or may vomit; another may be purged and collapsed. Over and above the examination of the urine as a never-to-be-neglected part of a first examination in every case, it is probable that scantiness of the urine is the most constant symptom pointing to defective renal activity in these cases.

But it must not be forgotten that sometimes in albuminuria the dominant feature, as already told, may be that of anæmia; that in no small number there is no dropsy or at most only an indefinite puffiness; and that it happens occasionally that a child is said to have died suddenly without any pronounced symptoms of any sort, and the left ventricle of the heart is found after death to be dilated.

Two other important considerations require notice here. In the first place, dropsy may be present, and acute nephritis, it may be presumed, also, without the existence of albumin in the urine. Secondly, and far more commonly, an albuminuria exists from which it would be a mistake to postulate the existence of a nephritis.

I take this first. I am of opinion that, while the presence of albumin in the urine in small quantity at one or two examinations may mean anything or nothing, the persistence of this symptom for any length of time without definite cause—such, for instance, as some passive pulmonary congestion or local scrofulous disease—is generally due to nephritis. I am familiar with the long existence of albuminuria without signs of ill health, but I am indisposed to admit that the existence of nephritis is thereby negatived. In five years past I have been on the watch for cases of the so-called functional albuminuria now so often spoken of, and, as the result of a very large number of examinations, the only conclusion I can come to is that it must be of great rarity. I do not doubt that it may exist occasionally; nevertheless, in my experience any albuminuria that is present again and again in the urine of any child or adult is as conformable to the hypothesis of the existence of nephritis as it is to that of functional disease. The symptoms of renal disease vary as the individual almost, and average health, if not common, is by no means unknown, and thus it is not at all safe to assume from the mere absence of symptoms that disease is absent. For example take the following case.

---

[1] On Renal and Urinary Affections, vol. ii,. Albuminuria, 2d ed., 1877.

A youth of sixteen years had scarlatina when a child of seven. It was a mild attack and no dropsy followed, but within two or three months albumin was found in his urine, and has never since been absent whenever it has been examined, and that has been frequently, and always by observers of the first reputation. At one time he was kept for six weeks on a milk diet without any influence on the albuminuria, and it still remains in quantity. He has never had any symptoms that could be attributed to renal disease, and seldom any of ill health. His urine has a specific gravity of 1022, containing albumin in quantity, with hyaline casts. His heart and arteries are quite natural.

Here, then, is a boy who has had albuminuria for nine years, remaining still in perfect health; yet can it be doubted, with the history before us, that he is the subject of a chronic nephritis, or that in the end he will succumb to a granular kidney? Nor is the existence of health amid stealthy disease unusual: its parallel may be seen in many another pathological process. There is pulmonary phthisis, which often progresses with intervals of recovered health. There is mitral stenosis, which exists for years before it becomes evident by loss of health. There is the kidney itself in adult life, which may often be known to be on the way to a granular state years before the organ becomes so inadequate as to pull up the patient. This principle of "compensation," as it is called, may be traced in all diseases, more or less, and in all is sometimes so complete for the time as to obliterate the evidences of disease. But the disease is there all the same. I will only add that, important as are these reflections as regards diagnosis, they are hardly less so with respect to prognosis and treatment.

Dropsy without albuminuria in any extreme degree is rare, but in slight degree it is probably not uncommon. Dickinson alludes to it, Henoch has notes of half a dozen such cases, and Hillier, Sée, Bartel, Duckworth, and the author all make mention of it as a condition with which they are well acquainted, or publish cases. Thomas[1] and Philipp (quoted by Henoch) have seen epidemics of this character. It is an open question whether this condition is or is not due to nephritis, but the more general opinion seems to be that it is so, because in some cases casts have been found in the urine; and in most, a very interesting observation in relation to the pathology of the dropsy, the urine has been remarkably scanty, in some amounting to temporary suppression. In Dr. Duckworth's case[2] the diminution of the urine was quite remarkable, and so also in one that occurred to me.[3] Such cases as I have seen have done well, but it is not always so. Henoch alludes to others in which the albumin, absent during the greater part of the illness, appears to some extent before death, and he quotes the statement of Litten[1] that there is a very grave form of hemorrhagic nephritis which is only revealed during life by some œdema of the face and hyaline casts in the urine. In mentioning authorities I must not omit the recent edition of Rilliet and Barthez, in which is given (tome ii. p. 694) a summary of these varied relations of the dropsy and albuminuria of Bright's disease, which is altogether admirable and quite accords with my own experience. It is indeed so much to the point that, at the risk of repetition, I give it in abstract. 1. Albuminuria may appear only after the onset of the anasarca. 2. Albuminuria may precede the dropsy. 3. Anasarca may return, in certain cases of relapse, without the reappearance of albumin. 4. Persistence of albuminuria is no impediment to variations in the intensity of the anasarca. 5. The albumin may disappear and the dropsy persist. 6. The anasarca may be wanting throughout the entire course of the malady.

[3] Guy's Hosp. Rep., Series III., vol xxvii., 1883–84, p. 198.

Complications.—Most of these have already been described in dealing with the symptoms. They come about in various ways. At one time it is the nervous system that seems particularly obnoxious to the defective elimination, when we may have to deal with sudden, violent, and repeated eclampsia, or obstinate vomiting. Convulsions are usually preceded by a diminution of the quantity of urine passed. They vary much in intensity, from a slight muscular twitching of some part of the face or extremities to a general epileptiform discharge affecting the whole body. There may be only one attack, or one may be rapidly succeeded by others again and again, when the condition is one of much danger.

At another time it is the tendency to œdema of the tissues and cavities that threatens. The anasarca may be so extreme that the skin will even give way, and large bladders form covered only by a delicate pellicle of cuticle. The skin is then very liable to a low form of inflammation or a wandering erythema, and this forms a dangerous addition to the already existing disease. One of the commonest and, on the whole, least ominous complications in this direction is ascites of moderate degree; but common, also, are hydrothorax and œdema of the lung, and both are dangerous, though probably more because they are indications of the severity of the disease than as an immediate cause of death in themselves. Hydrothorax is usually a slow formation, a part of the gradual water-logging. Œdema of the lung is often developed rapidly, and assumes the part of an acute bronchitis, as regards its physical signs, but the face is pallid, the respiration is much distressed, and the aspect of the patient betokens impending dissolution. Besides this, broncho-pneumonia is not uncommon: Drs. Ashby and Hutton, of Manchester, give notes of several such cases, in the annual abstracts of the Pendlebury Hospital for Sick Children.

Of others it may be said that they have no special peculiarity in children, and are, I think, indeed, less often seen. Yet at any age there is a tendency to inflammation of the serous surfaces, and, as regards the peritoneum, to a latent but rapidly-developing and lethal suppurative peritonitis. Happily, it cannot be said to be at all common. Barthez and Sanné lay stress upon diarrhœa as an occasional cause of rapid death, which may come on either spontaneously or be provoked by the purgatives oftentimes essential to the treatment of the disease.

---

[1] Charité-Annalen, VII. Jahrg., p. 162.

One other complication, hemiplegia, may be mentioned. It is rare, and for the reason that it is probably dependent on conditions other than those that lead to it in adult life. It is sometimes part of the phenomena of an attack of convulsions, and may persist afterwards, when it is possibly due to some cortical hemorrhage, thrombosis in the sinuses, or what not; in others, and more commonly, it is probably due to an embolus, and is dependent on cardiac changes secondary to the renal, and in all likelihood to a scarlatina that has preceded it. In this case the embolus may be washed from some inflamed valve or detached from some pouch of the ventricle, the clot having formed there during the time of failure of cardiac energy either from the fever or from the fatigue produced by the renal disease.

Prognosis.—It is very difficult to say anything that is really useful, the composite of symptoms varies so much for the individual. Barthez and Sanné give a loss all round of one in three. But it is very difficult to get at a reliable conclusion; probably some large and carefully-drawn statistics from general practice would best meet the difficulty, and it may be doubted whether from such a source the death-rate would be as high as this.

The elements for a prognosis in any particular case have already been indicated. In a case that is to do well the symptoms of the disease should show progressive amelioration, the scanty urine should become copious, the albumin should diminish steadily, and complications should be absent. The disappearance of the dropsy unaccompanied by lessening of the albumin at the time or shortly after is a bad sign rather than a good one. The occasional reappearance of a little blood in the urine, provided that the case is in other respects improving, is not of itself of any moment. The reappearance of lithates in an acute case is a good sign; and so also is the absence of disturbance of the general health. Bad signs, as a rule, are the persistence of dropsy and of albumin in quantity, persistent scantiness of urine, much pallor, albumin in quantity and dropsy little or none, the existence of albuminuric retinitis, the occurrence of erythematous eruptions on the skin. In adults we are accustomed to look to the pulse for certain indications of renal disease,—the hard persistent pulse, so characteristic and so well known,—and Dr. Broadbent has pointed out, with his usual acumen, that when these are wanting the prognosis is a grave one. I am sure that this is so: I have seen several such. Yet in children, as I have already said, the pulse-symptoms are not obtrusive, and are difficult to gauge, and more information will be gained by attending carefully to the sounds of the heart and to the position of the impulse at the surface of the chest. If the impulse goes outward and the heart-sounds become weakened, slow, and laboring, it is quite possible that there may be some sudden termination of the case; so that the friends might be prepared.

Treatment.—There are certain well-established rules for the management of nephritis that are common to all ages of life. These are that the surface of the body be kept in an equable temperature, that the bowels be kept freely open, and that the diet be mostly a fluid and weakly nitrogenous one. The object of these various measures is not far to seek. The skin should be kept in a warm atmosphere,—that is, in bed,—to keep it active and thus to prevent, as far as possible, the correlation between skin and kidney so important to a healthy organism, but likely to be harmful to a damaged viscus by goading it to spasmodic activity.

The patient is therefore kept in bed, between blankets. The skin is made to act freely by the free administration of liquid foods and water, and diaphoresis is aided by medicines such as acetate of ammonium and the pulvis ipecacuanhæ comp. Additional and powerful means of promoting perspiration are pilocarpine and the wet pack. All observers seem to agree that the former is a dangerous remedy in children, as it is often productive of vomiting and sometimes of alarming collapse. I have given it as a hypodermic injection in doses varying from one-fifteenth to one-twelfth of a grain to children of from four to eight or ten years, and it seldom fails to induce sweating, but I cannot say that I have seen much certain benefit from its use. Demme[1] has given five milligrammes to children under two years of age, from seven to ten milligrammes to those from two to six years, and as much as twenty-five to those above six years, but I would not recommend the larger dose. One injection a day is usually sufficient. It can also be given by the mouth, and perhaps better so to children, in doses of from one-eighth to one-fourth of a grain, either in tablet or in syrup and water; but in any case it is best to use it with caution and to feel one's way.[2]

I much prefer the wet pack. A thin blanket is wrung out of hot water, and the child, divested of all its clothing, is wrapped in it from chin to feet; then a dry blanket is wrapped round it and loosely covered with a mackintosh. After an hour or so the wet pack is removed, and the child swathed in a dry blanket. This is a powerful means of producing a free action of the skin, and with care I do not know that it is ever harmful, but the body-temperature must be watched meanwhile, and the pack should not be continued for any excessive length of time. At the Evelina Hospital for Children we at one time applied a continuous pack in several cases, but it was productive more than once of a sudden rise of temperature to a rather alarming height, and in another case, although the nephritis was cured, an acute general dermatitis exfoliativa was caused which was many weeks before it got well. Dr. Carpenter, the resident medical officer at the Evelina Hospital, has published these cases in the *Practitioner* (1888).

---

[1] Jahrbuch für Kinderheilkunde, xvi. 369.

[2] See also Henoch, op. cit., for a still more doubtful advocacy of this drug.

In addition to these measures there are warm baths and vapor baths, which, provided that chills are avoided on getting in and out of the bath, are some of the least harmful means of relieving the kidney; yet even measures so simple as these are not without drawbacks if used indiscriminately. Henoch has occasionally seen a warm bath followed by a fresh accession of hæmaturia after each bath. Dr. Dickinson also speaks in words of warning. He says that much mischief has probably been done by purging and sweating, although in their proper sphere they are invaluable. Barthez and Sanné consider baths most suitable for chronic conditions and when the respiratory tract is healthy. If the disease is acute and the lungs are implicated ever so little, they are dangerous. They have seen sudden œdema of the lungs and death follow their employment several times; and, although I cannot say that such has been my own experience, I think the statement is well worth attentive consideration in conjunction with what has been said regarding the continuous pack.

Alkalinity of urine is thought by many to favor the return of the kidney to its natural state, and citrate of potassium in requisite doses may be given with that object.

The question of diuretics has been much discussed, and if by diuretics be meant all such remedies as are supposed to act directly upon the kidney, such as squill and broom, I can only say that after many trials I have long discarded them as quite inefficacious under the circumstances in which they are required to act. The only diuretics of any value are digitalis (and possibly other remedies of that class, such, for example, as strophanthus), salts such as citrate of potassium and benzoate of sodium, and water. These are all of value,—the cardiac tonics probably by their action on the circulatory system, the water by diluting the blood and making it less obnoxious to the tissues, and the salts by favoring the conversion of the urates into other and less irritating products. Caffeine, too, may receive favorable mention for occasional cases. Its value is probably due to its action on the circulatory and nervous systems rather than to any local action on the renal cells, although in combination with benzoate of sodium and ammonium it is unquestionably at times a useful and potent diuretic.

There are no drugs that will directly lessen the quantity of albumin that is passed, but I doubt whether the drain of albumin is often sufficient to do any serious harm: the importance of the quantity is chiefly in its being an index of the state of the kidney. If, however, after three or four weeks the albumin remain in large quantity, and blood continues to reappear from time to time, or the pallor is considerable, iron sometimes does much good. I give it sometimes as the tincture of the perchloride, sometimes as the acetate,—a preparation that is usually well borne. Henoch speaks well of tannic acid and of ergotine. The former I have often made use of, the latter sometimes, but I cannot say that I have seen any benefit from either.

Failing with iron in the later stage, I think that maltine and cod-liver oil are sometimes of use. There must be something very peculiar in the change in nutrition indicated by the fatty changes of chronic parenchymatous nephritis, and when it goes, as is often the case, with extreme pallor it has often occurred to me to treat the anæmia rather than the renal inflammation. But it is, I think, certain that a strong meat diet makes matters worse, and where iron tonics fail to mend matters much it becomes a necessity to apply to those foods which will aid us without overtaxing the damaged viscera. I have seen cases where it seemed that the administration of cod-liver oil and maltine, once or twice even of brandy, was the starting-point of recovery, and for exceptional cases I am not prepared to prohibit any article of diet, even meat or alcoholic stimulants.

To sum up, then, in a simple case the child is at once put to bed between blankets; its diet is reduced to milk food, varied as much as possible by the introduction of vegetables, ripe fruits, cream, etc., with the free administration of soft water; a daily warm bath is given,—if necessary, a wet pack or vapor bath; the bowels are kept freely open by an occasional purge, and the acetate of ammonium and perhaps a little pulvis ipecacuanhæ comp. are administered internally.

If the urine becomes scanty or convulsions threaten, the wet pack is repeated at intervals of four or six hours, a large poultice is applied to the loins, and dry or even wet cupping may sometimes be resorted to with advantage.

The various complications may be taken *seriatim.*

Convulsions.—The child should at once be divested of all clothes and placed in a wet pack, or, as some may prefer, the loins may be dry-cupped freely, and a large poultice applied over them and changed every three hours. The wet pack is to be used concurrently with these measures.

The bowels are to be freely opened by two or three grains of calomel, and, after the action, twenty grains of bromide of potassium may be given as enema, or eight or ten grains by the mouth if the child can swallow. In the majority of cases these measures will prove sufficient: the patient slowly comes round from the drowsy state following the fit, the urine is secreted more copiously, and then the measures already described may be resumed. But in the more severe cases, where one fit follows another, or other of the lesser convulsive movements seem to threaten, the vexed question of venesection must be considered. I cannot speak from experience, for I have never, that I remember, bled in such a case; but it is for such cases that most writers on diseases of children advise that either cupping to the loins or leeches to the mastoid process should be applied. For my own part, I should still prefer an ice-bag to the head, and the administration of chloroform and bromide of potassium and hydrate of chloral, either by the mouth or by the rectum. Dr. Barr speaks strongly in favor of benzoate of ammonium in full doses for preventing a recurrence of the fit, and, although I do not remember to have ever made use of it in precisely these cases, I am so impressed with the value of the benzoate of sodium for aiding elimination by the kidneys in renal disease, as I have already said, that I certainly think it might prove useful here.

Vomiting may be present at the onset of the disease, when it probably will not call for special treatment, or it may indicate a grave amount of mischief, and will be best combated by measures already detailed which aim at procuring depuration of the juices by viscera other than those diseased. Should local remedies seem advisable, half-hourly drop-doses of tincture of iodine in a teaspoonful of water may be tried, or the old-fashioned but effective bismuth with hydrocyanic acid and bicarbonate of sodium. Nitroglycerin is sometimes useful in adults and might possibly be so also in children. Much, too, may be done with diet. Skimmed milk or whey, iced, will often be retained when other things are vomited. A little iced champagne, too, is a seductive to the stomach well worth a trial.

Diarrhœa must be treated by ordinary measures.

Dropsies of the serous cavities may require paracentesis for the relief of immediate symptoms, but it is not often so, particularly as regards hydrothorax. It is far more common to have to tap the abdomen, sometimes because of the amount of fluid in the abdominal cavity, and sometimes with the object of inducing, by the removal of pressure, a better excretion of water from the kidney. I always make use of a very fine canula, such as that called a Southey's tube, but made longer to allow of penetration of any additional thickness of the abdominal wall. A tube of this kind may be left in the peritoneum for ten or twelve hours without any risk and with little discomfort. It will usually become blocked with a little lymph by the end of this time or probably before, but ten or fifteen pints may be withdrawn in this way, to the great relief of the patient. The chest must be aspirated if any operation is necessary; withdrawal of the fluid by other means is a remedy of the last resort.

Anasarca must for the most part be treated also by occasional free purgation and by the vapor bath or other sudorific. In extreme cases I prefer simple acupuncture to the use of Southey's tubes, as less worrying to the child.

But I have no doubt of the utility of digitalis and strophanthus, and I have certainly seen good results also from caffeine or its combination with benzoate of sodium. Some advise that the fluids imbibed should be limited in these cases, arguing, with great appearance of probability, that the more fluid taken in, the more is the anasarca likely to be increased. But, so far as I have been able to judge from actual cases, I do not think this objection to free imbibition well founded. On the contrary, I have occasionally carried out this suggestion, and I have invariably found that the albumin has increased in amount and the patient has been worse. The treatment of the anasarca is indeed in some cases a very anxious question: do all we can,—drugs, baths, puncturing the legs,—nothing seems to dissipate or even to arrest it, and this is particularly so in adults—I cannot say it is in children

—where the chronic nephritis exists without the usual concomitant of high arterial tension.

Suppression of urine must be treated in much the same way as an attack of convulsions, omitting, of course, such remedies as are aimed directly at the arrest of the convulsive movements. A brisk aperient is given, the loins are freely dry-cupped and then poulticed, and the body is either wet-packed or treated to a vapor bath. Acetate of ammonium and citrate of potassium are given freely by the mouth, and plenty of watery drinks, such as barley-water, whey, soda-water, and lemonade.

Pulmonary œdema is a very dangerous symptom, and it is to be prevented rather than treated. When it has set in, a dose of compound jalap powder or of scammony powder should be given at once, and small doses of digitalis mixture, digitalin, or strophanthus given at frequent intervals. Brandy or champagne will also, in all probability, be required.

Hæmaturia seldom calls for treatment. Even when it is profuse it usually ceases within a short time; and when it appears and reappears merely to the extent of tingeing the urine it is of no moment as a hemorrhage. But, if necessary, hamamelis, ergotine, or tannic acid may be given.

The *dilated heart* of renal disease is usually a concern of the left ventricle, but I may say, in passing, that I have occasionally met with it on the right side, and even on the right side alone, when I have been obliged to assume that the arterial spasm in some cases is more pulmonary than systemic. But it is mostly the left ventricle that suffers, and it is to the clinical evidence of this that our attention should be directed with the view of preventive or other treatment. The evidences are twofold. In the first place, some indications may be gathered from the character of the heart-sounds and the features of the muscular action. These have already been described. The irregular or halting action, and the impression of labor conveyed by the length, want of sharpness, or shuffling quality of the systole, indicate unmistakably to the attentive ear that the ventricle finds a difficulty in overcoming its work, and that it requires such aid as can be afforded it. In the next place, in many cases other evidence can be obtained by a careful scrutiny of the position of the impulse on the chest-wall. It is therefore imperative in all cases of acute renal disease that the heart should be examined daily if possible, or at any rate at frequent intervals, and if there be any evidence of heart-failure it may be obviated or lessened by appropriate measures. These are little different from those that have already been mentioned, but they will vary somewhat with the case, one measure proving more useful in one case and another in another. Thus, a free hydragogue cathartic is one of the most useful methods of relieving a jaded heart. With it, it may be advisable to give a little alcohol. The wet pack or vapor bath may do something; alkaline diuretics also. But, as a general rule, digitalin, digitalis, strophanthus, and caffeine are the remedies most useful. It is my belief that by carefully watching the heart, and giving digitalis or one of the other remedies when the first symptoms of heart-failure appear, a dangerous crisis may in many cases be passed over. I usually give the tincture of digitalis in four- or five-minim doses every three or four hours, continue it for a day or two, and then leave it off for a day or two and take to it again if necessary. But small doses of digitalin, the one-hundred-and-twentieth of a grain, may be given frequently instead; strophanthus also in two- to five-minim doses, or caffeine in doses of one or two grains. The latter I usually combine with benzoate of sodium; this forms a solution in water which can be sweetened or flavored as necessary.

There are many other remedies that might prove of service occasionally. Thus, sparteine sulphate is recommended by some as a good heart-tonic. It may be given, one-fourth grain for a dose, three or four times daily, either as a granule or in solution. Paraldehyde, of unquestionable service in the laboring heart of old renal disease in adults, might be of service here. Five or ten minims may be given in almond mixture or with a little rectified spirits, tincture of orange, and water, either occasionally, or regularly two or three times a day; and, if time serve, strychnine, by subcutaneous injection, in drop doses of one-hundredth of a grain, is one of the most valuable cardiac tonics that we possess.

Of the dropsy that is unaccompanied by albuminuria it is hardly necessary to speak, but this much may be said, that the few such cases which I have seen have all been readily amenable to rest in bed, the wet pack or vapor baths, and alkaline diuretics and diaphoretics. These measures, with perhaps the addition of a little digitalis, are the proper ones to adopt in such cases. For those who have once had a pronounced attack of renal inflammation it is advisable that they should in the future be more carefully preserved from chills and undue exposure than heretofore. I have seen several cases in which a history has been given of recurrent attacks of slight puffiness of feet or face in the course of several years, with intervening periods of what have been described by the patient or the parents as times of health. Henoch also states that he has several times known a chill, as from a bath in the sea, produce a fresh attack, and he considers the kidney a vulnerable organ after an attack of scarlatinal nephritis.

CHRONIC BRIGHT'S DISEASE.

Synonyme.—The granular kidney.

I have in the early part of this article given reasons for confining the meaning of the term "chronic Bright's disease" in children to the granular kidney, and it will be unnecessary to say more now. Of two hundred and thirty cases of granular kidney examined in the post-mortem room of Guy's Hospital in the ten years from 1873 to 1882, there is no case under ten years, and only one, a female, under twenty. But this is, as I have said elsewhere, a matter of interpretation. Some would call all kidneys granular which are small and irregular on their surface, but even with this liberal interpretation granular kidney is not and could not be a common disease in children. Any one who has ever given the smallest consideration to the physiology of child life and to the pathology of the granular kidney will admit this at once. The questions of most interest are, does it occur? and, if it does, what are its causes? and the interest of these lies chiefly in their throwing light upon the natural history of the disease in later life.

That it does occur can at once be proved by cases. Records of many such are to be found scattered through the medical periodicals of recent date, and I give short notes of two, one not hitherto published, that have been kindly furnished to me by Dr. Henry Ashby, of Manchester.

Margaret B., aged ten, was admitted into a surgical ward of the Pendlebury Hospital for Sick Children for rickets and deformity of the legs. She had never been a strong child, and her legs had been crooked ever since she began to walk. Nothing peculiar had been noticed about her, except that during the last two years she had suffered a good deal from thirst, getting up usually once in the night to pass water. Recently she had had headaches, and labored breathing and coma on the last two or three days. She was a small girl, with deformed tibiæ, and when in bed it was noticed that she had urgent dyspnœa. Respiration 26, pulse 110, temperature subnormal. She was much distressed and somewhat cyanosed. The examination of the chest revealed nothing abnormal: the cardiac beat was in the fifth space, half an inch inside the left nipple. Later in the evening the dyspnœa became more urgent and she more cyanosed, but without apparent cause. Respiration 36, pulse 120. The urine was passed under her, and none could be obtained for examination. During the night sharp diarrhœa came on, she became unconscious, moist râles appeared in the chest, and she died in a convulsion the day after her admission.

Autopsy.—Lungs gorged, but otherwise normal. Heart: left ventricle wall somewhat thickened. The kidneys were very small,—both almost exactly the same size,—one and eight-ninths inches in length, one and one-quarter inches broad. They were firm and pale; the capsule stripped with difficulty, tearing away pieces of the cortex; surface of the cortex granular; its section so wasted that hardly any remained, fatty-looking and mottled. The kidney, of which a slice is now before me, is a striking specimen of the active interstitial form of the disease. By this I mean that the disease is one of copious nuclear growth, and not one of mere fibrosis with atrophy. Thick irregular bands of highly-nucleated material spread from the cortex downward to the medulla, and within them are thickened and shrivelled capsules and wasted tubes. They have a basis of fibroid material, and show well-marked puckering or cicatrization. Outside them are tracts of comparatively healthy tubes.

The following case is from the published abstract.[1] It was that of a girl, aged eleven and three-fourths years. The history is imperfect, but the child had never had scarlatina, and her ailment dated back only two or three weeks. Three days before her admission her face began to swell and her breath became short. She was in much distress, with dilating alæ nasi. Pulse 120, weak; respiration 44; temperature 99.4° F. The resonance at the left base was impaired, and coarse râles were heard throughout both lungs. The first sound of the heart was weak, the second accentuated; no bruit; apex-beat in the fifth space outside the left nipple-line. The urine was pale, clear; no deposit; specific gravity 1015; one-half albumin. She was treated with jaborandi and packs, and passed gradually-increasing quantities of urine; but the quantity of albumin remained about the same (no casts were ever found), and the œdema also, and she gradually sank.

---

[1] Abstract of some of the Medical and Surgical Cases treated at the General Hospital for Sick Children, Pendlebury, Manchester, 1883.

At the autopsy these points were noted. Much œdema of the subcutaneous tissues. Right lung: twenty ounces of fluid in the pleura, the lung semi-collapsed and œdematous. The left lung was gorged and œdematous. The heart weighed eight and three-fourths ounces. Right auricle wall very thin; right ventricle also, and cavity dilated. The left ventricle very thick; cavity slightly dilated. Peritoneum contained much fluid. Kidneys: right, two and one-fourth ounces in weight; left, three-fourths of an ounce. Right, small granular on the surface; capsule thickened and adherent; cortex very narrow, hardly existing in places; pale, infiltrated with urates; ureter and calyces dilated. Left, very small, merely a vestige; ureter and calyces dilated; very little kidney-substance; capsules adherent; surface granular; cortex and pyramid infiltrated with urates; both ureters dilated; no obstruction detected. Microscopically there was great increase of fibroid tissue between the tubules, in many places infiltrated with leucocytes; the Malpighian corpuscles surrounded by fibroid tissue, some of the glomeruli having undergone a hyaline degeneration, many of the tubules being dilated and filled with urates.

One other case may be mentioned, although beyond the period with which this article deals; but the disease probably commenced at the age of twelve years. A girl of eighteen years was admitted into Guy's Hospital under Dr. Wilks. She had had scarlatina six years before, followed by swelling of the feet. From this time there is a gap in her history until six or seven months before her admission. Since then she had had sickness and shortness of breath. Her legs and face had been swollen for a month only. She was very ill. There was some œdema of the legs, and, to a less extent, of the abdominal wall also. The urine had a specific gravity of 1010, and was very albuminous. Death occurred within a day or two, and upon making the autopsy the kidneys were so much contracted as to weigh three and a half ounces only. Their surfaces were red and sandy or minutely granular in some parts, bossy and fatty-looking in others. On the whole they were fawn-colored. The wasting was more extreme in one: it weighed only one-half to three-quarters of an ounce. The heart weighed ten and a half ounces, the left ventricle being remarkably tough, although not thick.

With respect to the causes of this state of things, it occurs oftenest after scarlatina, and is probably the result of an insidious subacute inflammation insufficient to give rise to dropsy of more than a slight and transient character. I have seen cases where the anasarca was thus temporary, but where headache and sickness had frequently recurred since, so as to lead one to suppose that the process had been a long-existing and continuous one. But it cannot be doubted that other causes exist, and of these I suspect that gravel and calculus are far more common than has been hitherto taught. At any rate, I have been struck, both in the cases I have seen myself and in those recorded by others,—one of the cases just detailed is an example,—with the frequency with which a shrunken kidney is found associated with a dilated pelvis. A previous obstruction is not absolutely proved by this condition, because all muscular structures falling into disuse become deteriorated in structure and toneless in function, and the dilatation might conceivably come about in that way, and it must be confessed that one can seldom demonstrate the presence of a stone. Nevertheless I hold to the opinion, for calculi are seldom large in childhood, small calculi passing or impacted in the ureters are by no means uncommon, and pathological investigation of recent years has shown that an ascending nephritis, as it has been called, supplies an adequate hypothesis for the setting in progress of a creeping disease such as this.

Again, there is no reason why, as an occasional occurrence,—since we have found that it must be admitted that a primary nephritis other than scarlatinal is not uncommon and is very equivocal in its symptoms,—the overlooked nephritis from an ordinary chill should not lead to such a result,—and, I may also add, the occasional action of various blood-poisons, of which I remember to have seen several years ago a striking example. A marked specimen of a granular kidney was sent to me by Dr. Wilkin, of Beckenham, with this statement, that the girl (about eighteen years old) had been admitted to the hospital and died within a short time from chronic Bright's disease, and the only cause that could be assigned was that she was known to have suffered once from lead colic several (I think eight or ten) years before.

This is, I think, all that can be said of the causes of the granular kidney met with in childhood. As regards symptoms, in the absence of thickening of the vessels and other characteristics, it would appear to be a malady not unlikely to be overlooked until death is somewhat suddenly ushered in, either by convulsions and coma, or by dyspnœa, vomiting, perhaps diarrhœa, and collapse. But I would again insist upon the occasional existence of severe thirst and polyuria in any form of chronic nephritis.

Once the diagnosis is made, the prognosis can only be a hopeless one, even if the issue be some time delayed, and the treatment must follow the lines that have been indicated in the previous sections.

SURGICAL DISEASES OF THE KIDNEY.

By HENRY MORRIS, M.D., F.R.C.S.

PERINEPHRITIS AND PERINEPHRIC ABSCESS.

Definition and Pathology.—Perinephritis is inflammation of the cellular and adipose tissue surrounding the kidney. When the inflammation has run on to suppuration, perinephric abscess is said to exist. In some cases the suppuration is wide-spread and diffused; in others, only a single, circumscribed, and more or less extensive abscess is present; in others, again, the whole of the perinephric tissue is thickened and indurated by inflammation, and broken down in places into circumscribed collections of pus. If the pus is not evacuated by incision it may burst through the diaphragm into the colon, ureter, stomach, or small intestine, or it may present at the sacro-sciatic notch, or burrow inward across the middle line to the opposite loin. In acute cases the fibrous capsule of the kidney may be very vascular and red, and the cellular tissue surrounding it may be infiltrated with serous fluid. Blood is sometimes effused beneath and around the fibrous capsule. The pathological changes observed in the kidney itself are frequently those to which the perinephritis was due; in other cases the renal changes are secondary to the inflammation in the perinephric structures. There may be general softening of the kidney, but without any purulent dépôts in the secreting substance, or suppuration in the pelvis or calyces of the organ, or the whole or a part of the kidney may be quite liquefied by the solvent action of the surrounding pus and the softening influence of the inflammation.

In some cases pus is found beneath the fibrous capsule of the kidney. The fibrous capsule is sometimes so intimately adherent to the surrounding tissue that they cannot be separated.

History.—Since the time of Rayer three classes of perinephric abscess have been recognized,—namely, (*a*) primary extra-renal abscess, or that which is independent of disease within the kidney; (*b*) secondary abscess caused by extension of inflammation from the kidney, but without urinary infiltration; and (*c*) secondary abscess due to a fistulous opening from the kidney into the surrounding cellular adipose tissue. Abrasions of the last kind are commonly, but not invariably, due to renal calculus. Previous to

Rayer's time, only the first of these classes had been systematically recognized or described.

Etiology.—Perinephritis and perinephric abscess have been met with at all ages from five weeks old upward. They have been oftenest encountered in males, but are very frequent in females. As the result of injury they may occur in either sex and at any age. In some instances, but few by comparison, they are idiopathic and quite simple in their course and termination. When secondary to disease in the kidney or spine they often run a complicated course and terminate fatally. Blows, strains, punctured and incised wounds in the loins; severe bruising of the loin by the rolling and tossing of a vessel at sea, or by the jolting of a carriage during a long ride over a rough road; over-fatigue in walking; unaccustomed muscular exercise, as digging; falls upon the loin; and simple debility, have all been assigned as causes of primary abscess. A sudden chill, especially after sweating or exposure to great heat, is an exciting cause; so also are various depraved states of the blood, such as occur after an attack of continued or exanthematous fever or any other severe illness. Operations on the testicle, bladder, and vagina, and the formation of pus in the broad ligament of the uterus, have been followed by perinephric suppuration. The most frequent causes of secondary abscess are suppurative pyelitis, nephritis, or pyelonephritis, whether due to calculus, tubercle, cancer, hydatid, or cystic disease, or to suppuration spreading along the ureters from the bladder. In children some of the conditions which in adults commonly bring about renal suppuration are not operative, such, for instance, as prostatic enlargement and organic stricture; but vesical calculus, neglected phimosis, and congenital contractions of the urethra are followed by precisely the same kind of results.

The evidences of chronic perinephritis are often seen after death from these diseases of the lower urinary tract; and in acute cases of the kind the renal capsule is highly vascular and numerous small abscesses may be found in the inflamed surrounding tissue. If time is allowed, these abscesses coalesce and may burrow far and wide, if they do not burst internally into the colon or through the diaphragm or peritoneum. In some cases, without there being any perforation of the renal capsule, inflammation of the perinephric tissue is caused by the presence of miliary abscesses in the cortex of the kidney; in others, by the irritation of repeated attacks of renal colic. Perinephric abscess may arise from inflammation and atrophy but without suppuration of the kidney, and also from tumors of the kidney. Renal fistula due to calculous pyelitis is a very common cause of perinephric suppuration; so also is disease of the spinal column. Inflammation and suppuration may spread along the veins or retroperitoneal tissue from disease of or operation upon distant parts, such as the rectum, urethra, urinary bladder, testicle, tunica vaginalis, or spermatic cord. A pin perforating the colon, an empyema ulcerating through the diaphragm, a typhoid or scrofulous ulcer of the ileum, typhlitis, and perityphlitis, have occasionally excited abscess about the kidney.

Symptoms.—The symptoms of perinephritis vary with the cause and the acuteness of the disease, and are by no means always well pronounced. When secondary to disease of some other organ, perinephritis is often masked by the primary affection. When primary, it is often obscure or insidious in character. On the other hand, the symptoms may be evident from the first, and a large fluctuating tumor be developed in the flank in from ten to fourteen days, attended with severe constitutional disturbance.

Perinephritis may often be detected before suppuration has commenced, by attention to the following signs:

The spinal column is preternaturally stiff, and curved in the antero-posterior direction, or possibly it will deviate a little from the affected side. There is stiffness in walking, and the body is inclined over to the affected side; so much so, in some cases, that the crest of the ilium is in contact with the lower ribs. Whilst standing, the body will be flexed upon the thigh of the affected side, and the hand of the same side will rest supporting the trunk on that thigh. The continued flexion of the thigh causes some lordosis in walking. If an effort is made to stand, without support, on the affected side, the body is thrown far over towards that side, and the opposite thigh and leg are strongly flexed. Stooping will be difficult. Whilst lying on his back the patient will not extend the thigh beyond one hundred and sixty degrees, and in more severe cases not beyond one hundred and thirty. There is pain in every movement of the trunk in severe cases, so that the patient may not be able to turn over in bed. Flexion of the thigh will not give pain, but complete extension will not be possible, and its attempt will cause discomfort, if not pain. Abduction and adduction will probably be uninterfered with, but there may be some difficulty in adduction. The patient will be able to stand on the affected limb alone, in the manner described above. In mild cases the limb may look straight whilst standing, but when lying or sitting on a hard mattress the ham cannot be made to touch the surface. Occasionally it has been noticed that the thigh is rotated outward; when this is so the heel of the affected side during the standing rests upon the dorsum of the other foot. In this state the second stage of hip-joint disease is simulated.

When knee-joint pain is complained of we must beware of mistaking perinephritis for morbus coxæ. With pain in the knee, lameness, and muscular rigidity about the hip-joint, it is too often concluded that we have sufficiently strong evidence of morbus coxæ; but a cautious examination is requisite before we commit ourselves to this diagnosis.

In perinephritis there is no atrophy of the muscles of the thigh, no shortening of the limb, no fulness or tenderness on pressure about the head or trochanter of the femur, no tenderness or pain on succussion or passive motion of the hip-joint, no tenderness over the sacro-iliac joint, and none on percussing the spinous processes or on succussion of the spinal column. The tenderness in the loin will be above the crest of the ilium, and one or two inches at least to the side of the spines of the lumbar vertebræ. The tongue will be coated, the temperature raised commonly to 103° F. and often to 104° or higher, and the urine will be acid and without blood or pus, though there will be abundance of lithates and there may be some albumen.

Thus, with feverishness, without tenderness over the spinal column, and with symptoms pointing to an inflammatory affection on one side of the column, there is an absence of the characteristic signs of disease of the hip and sacro-iliac joints, though a very similar alteration in the attitude, and much the same limitation of muscular mobility of the affected side.

In perinephritis there is no tumefaction to be felt in the loin or around the kidney, as in perinephric abscess.

As recovery by resolution occurs, the tenderness in the loin subsides, the temperature declines gradually to 100° F. and then to normal, sitting is less uncomfortable and walking more easy, flexion of the thigh is no longer maintained, and extension in dorsal decubitus can be fully and easily accomplished. The tongue gradually cleans, and the bowels act with regularity as usual. At length all inclination of the trunk to the affected side is discontinued.

When perinephric abscess is forming there are usually the ordinary signs of deep suppuration: rigors, high temperature, sweating, furred tongue, thirst, loss of appetite, perhaps vomiting, and delirium, in the acute cases; constipation, foul tongue, loss of appetite, slight elevation of temperature, in the chronic. In other words, the symptoms will be more or less severe according to the acuteness of the inflammation. In old and weakly persons, and when the inflammation is chronic, the symptoms may be altogether masked, until the abscess, by its size and pressure upon surrounding structures, forces itself upon the attention. In some subacute cases the only symptom for several weeks before pus was discovered, or even suspected, has been lameness, attributed to morbus coxæ or to rheumatism.

The febrile temperature does not always take the same course: in some cases it is like the course of typhoid, running continuously high; in others it is intermittent, and suggestive of malaria or pyæmia. Obstinate constipation is a very frequent symptom, and is doubtless due to the loss of muscular effort or to the patient's dread of employing it.

Of the *local symptoms*, those due to pressure are more marked in perinephric abscess than in perinephritis. Pain is one of the earliest and most prominent indications. Its common seat is the loin and side of the abdomen, but sometimes it shoots down the thigh or into the hypogastrium, scrotum, penis, testes, or groin. This wide diffusion of pain is explained by the anatomical distribution of the nerves of the lumbar plexus, which traverse the renal region. It is in one case of a dull aching character, in another darting or pricking. Occasionally it may be felt in the knee, as in coxalgia. In most cases it continues and increases until the pus is evacuated; but in other cases the severity of the pain diminishes temporarily, or disappears entirely for weeks or even months, encouraging a delusive hope that recovery has taken place. If the loin be compressed between the two hands the suffering caused is in some instances very acute.

The affected side will often give to the surgeon the sense of increased resistance and weight long before pus has formed. This condition will be best detected by lifting, as it were, each loin by the flat hand placed behind each ilio-costal interspace. A feeling of weight in the side is sometimes experienced by the patient. Later on there will be dulness and swelling in the ilio-costal interspace. The skin in the loin may be either waxen and œdematous or congested. After a time deep-seated fluctuation may be detected in place of the hard resistance previously felt; but this will depend much upon the thickness of the abdominal parietes.

Retraction of the testis has been noticed in some cases: it is most likely to occur when perinephric abscess is caused by calculous pyelitis, but is not restricted to such cases.

Œdema of the foot and ankle may precede for many weeks every other sign of perinephric abscess.

A peculiar lameness is often an early symptom, and is due to the flexed position in which the thigh of the affected side is retained. Sometimes the patient walks with the body bent forward and inclined to the affected side, with the hand of the same side resting on the middle of the thigh; and he sits on one tuber ischii, so as to relax the psoas muscle of the other side. The psoas muscle may serve to guide the pus either downward to the groin or upward beneath the arcuate ligament of the diaphragm into the pleural sac or the lung.

An inability to extend the thigh of the affected side is sometimes an early symptom; the limb is kept flexed on the abdomen, and any attempt at extension causes pain. Other movements, such as adduction, may be painful; or there may be anæsthesia or motor paralysis of the thigh of the diseased side.

The pus contained in some cases is quite odorless, in others fetid; in a few it has a fæcal odor, even though no fistulous communication with the bowel exists.

The urine may contain albumen, from pressure on the renal vein, or pus and blood, due to primary renal disease; or it may be quite unaffected in quality and quantity. Vesical irritation is an occasional symptom. Sometimes there is pleurisy or pneumonia on the affected side masking the perinephritis, and the patient appears to be suffering exclusively from disease within the chest.

As soon as the pus is evacuated the temperature falls, the pain vanishes, the appetite returns, and the flatulence and constipation disappear. The patient rapidly recovers, provided the incision of the abscess has been made before the pus has burrowed too widely or the inflammation has set up some dangerous complication.

Diagnosis.—The affections which may be mistaken for perinephritis or perinephric abscess are lumbago, nephralgia, various organic diseases of the kidney, spinal caries, perityphlitis and perityphlitic abscess, splenic and hepatic tumors, fæcal accumulations in the colon, empyema, pneumonia and abscess of the lung, typhoid fever, morbus coxæ, and psoas abscess.

In lumbago the pain is felt on both sides of the spinal column, is unaccompanied by fever or swelling, and does not shoot to the front of the abdomen or the groin. In nephralgia the pain is paroxysmal, and the local signs of perinephritis and the flexion of the thigh are wanting.

The diagnostic signs of organic renal diseases are described under their respective headings. In disease of the spinal column there is pain around the trunk along the course of the spinal nerves, the body is held stiff, and there is no rotation or inclination of the trunk towards one thigh. In perityphlitis the pain, swelling, and tenderness are in the iliac fossa, not in the ilio-costal interspace. Fæcal accumulations and the pain they cause are removable by aperients. Empyema and pneumonia have their own special signs, and never give rise to thigh-flexion. In typhoid there are no evidences of local inflammation in the loin, and there are the characteristic temperature and tongue and rash, the tumid abdomen and the big spleen.

From morbus coxæ perinephritis is to be distinguished by the high seat of pain and the painlessness of passive flexion, abduction, and outward rotation of the thigh without any attendant movement of the hip. Neither is there fulness of the hip-joint nor tenderness on pressure on the trochanter.

Prognosis.—The prognosis is always grave. The duration of the disease varies from two or three weeks to many months. In a few cases perinephritis ends in resolution before the suppurating stage has been reached. When suppuration occurs the prognosis depends chiefly on two things,—the early and free evacuation of the pus, and the cause of the disease.

If the abscess bursts into the lung, colon, or ureter, recovery may ensue if the cause of the disease is removable; or death may occur from pyæmia, hectic, or gangrene of lung. If the abscess bursts into the peritoneum, death quickly follows from peritonitis; if into the pleural cavity, empyema may terminate fatally. Syncope and apnœa may be caused by pressure of the abscess.

Treatment.—Primary perinephritis may be sometimes checked in its early stages by local blood-letting by means of leeches or the cupping-glass, and by hot baths and hot emollient poultices or stupes. When the acuteness of the symptoms has passed, or the inflammation is of the subacute or chronic character, absorption of the inflammatory products may follow blistering, or hot fomentations applied over some absorbent ointment, such as iodide of potassium or iodide of lead. The bowels should be well opened at the onset by a brisk purgative, and kept acting moderately by enemata or mild laxatives. Pain must be relieved by opium. The diet should be milk, beef tea, or something equally simple and as readily digested. As soon as the presence of pus is suspected it should be at once searched for with the aspirator, or by an exploratory incision in the loin. When matter is detected it should be let out through a free opening in the loin. There should be no waiting for fluctuation; the increasing fulness, hardness, and tenderness, and perhaps the commencing redness and œdema of the skin, are ample signs to demand an incision. The incision may be either vertical, oblique, or transverse, and after dividing the integument and muscles with a knife the suppurating area should be entered by the finger. The kidney should be explored with the finger, if possible, in the abscess-cavity, any loose sloughs of cellular tissue removed, and the abscess washed out with an antiseptic lotion. A drain-tube should be inserted, and the loin enveloped in a carbolic and lead lotion, or covered with a layer of antiseptic cotton-wool or gauze.

The wound must not be allowed to close too early, but the drain-tubes should be retained until they are forced out by granulations.[1] Even when no pus is found at the time of incision, much relief follows by the removal of tension, and pus often escapes some time after the operation. A fistula will occasionally persist for a long while after the discharge of the abscess.

HYDRO-NEPHROSIS.

Definition.—Hydro-nephrosis is the term given to the overdistention of the kidney with urine. It is a mechanical result of obstruction to the outflow of urine from the kidney, no matter whether the cause of the obstruction be situated in the urethra, bladder, or ureter, nor whether a renal tumor appreciable during life be formed by the dilated kidney or not.

Etiology.—The causes of hydro-nephrosis are (1) congenital and (2) acquired. Probably one-third of the cases in which a palpable tumor is formed have a congenital cause.

The congenital causes do not always give rise to hydro-nephrosis in infancy or very early life. There are several cases on record which show that a congenital cause has acted very slowly and incompletely, if at all, for a long time, but that after some, even many years, a hydro-nephrotic tumor has been formed and terminated fatally. Hydro-nephrosis due to a congenital cause is not, therefore, the same thing as "congenital hydro-nephrosis."

Among the *congenital causes* are twists of the ureter upon its own axis, undue obliquity, reduplications, folds, contractions, and other anomalies of the ureter. Sometimes the ureter has been found in part, or throughout, a fibrous cord; but in such cases the hydro-nephrosis exists at birth, though it increases afterwards.

In other cases the vesical orifice of the ureter is thick, rigid, and of merely pin-hole size; in others, again, minute cysts are developed within its mucous membrane; in others it joins the kidney at such an angle that urine can only with great difficulty flow through it. An abnormal renal artery may compress the ureter and so produce obstruction; so may an abnormal flap of membrane in the pelvis of the kidney or in the urethra.

The *acquired* causes of hydro-nephrosis are numerous, and, like the congenital, may be situated in, behind, or in front of the bladder. Impaction of calculus in the ureter, vesical calculus, fibromata and other growths within the bladder, the pressure of tumors, or of bands of organized inflammatory lymph, traumatic stricture of the urethra, contractions of the ureter from injury, such as kicks or blows, or the effects of the passage of a renal calculus, and undue frequency of micturition continued for a long period, are all well-authenticated causes of renal distention.

---

[1] Nutritious food, tonics, and possibly a limited amount of stimulants will be requisite.

Hydro-nephrosis may affect one or both kidneys, or may be limited to part of one kidney. The latter condition has been sometimes found in children having kidneys provided with double ureters: in some of these cases the cause has been congenital narrowing, in others tubercular disease of one of the ureters.

The proportion of cases in which hydro-nephrosis produces a palpable abdominal tumor is very small, compared with the frequency with which the condition is met with in the post-mortem room.

Pathology.—The pelvis of the kidney first becomes converted into a spheroidal sac, then the calyces are widened and stretched in every direction, and at length the capsule of the kidney is expanded, and what remains of the cortical and medullary substance of the organ becomes still further compressed and absorbed, until finally nothing remains but a more or less completely loculated bladder or cyst. Thus the tension exerted by the urine, which accumulates behind the obstruction, stretches the calyces and flattens and wastes the pyramids to such an extent that the calyces are converted into huge spaces or pouches jutting off from the dilated pelvis and separated from one another by slender septa formed by the wasted "columns of Bertini." On laying open the cavity of such a hydro-nephrotic cyst, nothing but a complete fibrous skeleton of the kidney will be seen. Sometimes nothing but a pellucid sac, with at most one or two, if any, septa, is present; generally, however, areas or a cortex of the secretory substance remain. In rare cases some of the dilated calyces are shut off from the others either by a layered calculus or by fibrous septa.

The walls of the sac are in some instances thin and translucent, in others thick, tough, strong, and even cartilaginous. The size of a hydro-nephrotic kidney may not exceed the normal size of a kidney; it may be even smaller. On the other hand, it may hold many gallons of fluid. The contents of the sac are rarely like natural urine. Often the fluid is odorless, gives no reaction with heat or nitric acid or with cupric tests, has a low specific gravity, leaves scarcely any residue on evaporation, and affords no evidence of urea or uric acid; in fact, it is only water holding a larger quantity of chloride of sodium in solution and containing a few epithelium-cells. This has been the character of the fluid in congenital as well as in acquired cases of advanced hydro-nephrosis.

Uric acid, urates, and oxalate of lime may be found in the fluid. At other times the contents of the cyst are turbid and mixed with muco-pus, or with blood-clot of old or recent date which gives a brown or red color to the fluid. At others, again, urea and chlorides may be found in it as in natural urine; and this, too, even in congenital hydro-nephrosis. Epithelial and granular cells, phosphates, and albumen are frequent constituents.

Sometimes the contents are colloidal in character. Cholesterine has also been found in the fluid.

Adhesions may exist between the sac and the surrounding parts, such as the peritoneum, omentum, mesentery, pancreas, liver, spleen, or intestines.

Symptoms.—Hydro-nephrotic distention affects each kidney about equally. It occurs at any period from birth to extreme old age, and is met with also in the fœtus. It is nearly twice as frequent in females as in males. When the dilatation is insufficient to give rise to a tumor, there are generally no symptoms characteristic of hydro-nephrosis. It must, however, be borne in mind that the whole round of morbid changes described above may be inflicted upon the kidneys without there being any sign of an abdominal swelling.

In some advanced cases in which there is no tumor, symptoms are excited simply by the obstruction: these are thirst, pain in the back, frequent micturition, total or partial or intermittent anuria, and obscure or pronounced pains in the abdomen.

When the disease is bilateral, uræmia may be looked for. Vomiting, convulsions, and febrile manifestations are occasional symptoms.

When a tumor is formed, hydro-nephrosis may destroy life by bursting into the peritoneum or in some other dangerous direction.

The tumor is dull on percussion, sometimes irregular or lobulated in outline, and frequently fluctuates. By its size it may cause much pain, displacement of viscera, disturbance of the action of the diaphragm, and thus of the lungs and heart, and it is especially prone to interfere considerably with the action of the colon, thus inducing constipation. In exceptional cases the tumor distends the whole abdomen, bulges out the lower ribs, and looks like an immense ovarian cyst.

If it arises from some painless cause, its development is unattended by any constitutional or local disturbance; but if from some painful cause, such as impacted calculus, the symptoms incidental to the particular cause will occur before the tumor makes its appearance, and will probably mask the development of the swelling.

The tumor has all the characters of a renal tumor, being situated in the flank, pressing backward and outward the parietes in the ilio-costal area, having the colon in front of it, and the small intestine either in front or thrust over to the opposite side of the abdomen, according to the bulk of the swelling.

The tumor extends beyond the median line of the body in about one-fourth of the cases, and in one-third of these it at length occupies the greater part of the belly.

There are instances of the tumor intermitting, being prominent at one time and not distinguishable at another. In many the tumor diminishes from time to time without actually vanishing, the subsidence of the swelling being followed by the discharge per urethram of an increased quantity of urine. In such cases the urine during the increased flow will sometimes yield an admixture of blood, pus, or mucus, but will always be of a lower specific gravity than normal urine. At other times, and in cases which do not subside or intermit, the urine gives no information whatever.

A hydro-nephrotic tumor may be quite painless when small; but when large the pain may be of the most agonizing character.

Diagnosis.—Hydro-nephrosis has to be diagnosed from renal abscess, perinephric abscess or extravasation, pyo-nephrosis, hydatid or serous cysts of the kidney, liver, or spleen, and, when of very great size, from an ovarian cyst or general ascites. Subsidence of the swelling followed by an increased excretion of urine is almost conclusive of hydro-nephrosis; but this rarely occurs, so that we have to rely on other points of diagnosis.

The absence of rigors and fever, of œdema and redness of the loin except when the hydro-nephrosis is of large size, the slow formation of the swelling, the existence of some obstruction to the passage of urine, and, lastly, the circumscribed outline of the tumor, will generally suffice to establish a correct diagnosis. The history of the case will often serve to exclude hydatid and serous cysts; if a hydatid vesicle has escaped with the urine all doubt is at once cleared up. Hydatid tumors of liver and spleen bulge more commonly towards the front than into the loin, and, moving with the organ in which they grow, are displaced more markedly during respiration. When of great size the hydro-nephrotic tumor is most likely to be mistaken for ovarian disease; but the direction of growth, its relation to the colon, and the evidence afforded by vaginal and rectal examination will generally prevent error.

Prognosis.—This depends on the cause of the obstruction, and on whether one or both kidneys are involved. If only one kidney is affected, life may be indefinitely prolonged, provided the size of the tumor is not great, or, if the tumor is large, provided relief from distention is afforded in good time. If the distention increases, death will result from the effects of pressure on neighboring organs, from rupture into the peritoneum, from suppression of urine, or from uræmia. Traumatic rupture of the cyst has been the termination of more than one patient. In most cases where the distention affects both kidneys, the cause of the hydro-nephrosis kills the patient, though even then one of the chief factors in producing the fatal result is the destruction of the glandular substance of the kidney, and the gradual cessation of the renal function.

In some cases the tumor has spontaneously subsided and never returned: this was the termination in six cases out of a total of forty-seven. There is always the fear lest a calculus or some affection of the opposite kidney may cause death by suppression of urine or by uræmia.

Treatment.—The treatment of hydro-nephrotic tumors is purely surgical; nothing can be done for them by medicinal remedies. When of small size, painless, and not on the increase, they may be left alone. When they cause trouble, either by their weight, pressure, or size, the aspirating-needle should be employed when there is any reasonable ground for believing that the cause of obstruction is temporary and that reaccumulation is not likely to occur.

An attempt might be made to overcome the obstacle to the passage of urine by friction. In children this treatment has met with some success; but it must be employed with caution, for fear of rupturing the cyst.

The use of the aspirator, sometimes repeatedly upon the same tumor, has been fairly successful. The best point to puncture is half-way between the last rib and the iliac crest, about two and one-half inches or more behind the anterior superior iliac spine, or else just anterior to the last intercostal space. If the tumor points at any spot, this should be selected for introducing the aspirating-needle. Aspiration may effect a complete cure, either by relieving pressure or releasing some curve or twist of the ureter. Sometimes a single tapping has sufficed; more often repeated tappings have been required before fluid ceased to reaccumulate in the renal cavity. When aspiration fails, nephrotomy through the lumbar incision ought to be employed. Care is required in aspirating not to puncture too far forward and thereby wound the peritoneum or provide for the escape of urine into the peritoneal cavity. It is not advisable to inject into the renal pelvis after withdrawing the contents any stimulating fluid, such as tincture of iodine, with a view to excite adhesions and contractions of the cyst-walls.

Nephrotomy is performed by cutting obliquely in the ilio-costal space through skin and muscles down to the distended kidney. As soon as the cyst is exposed through the wound in the loin it should be tapped and the fluid withdrawn; then the puncture-hole should be enlarged with a bistoury, and the edges of the cyst stitched to the edges of the wound in the abdominal parietes. If the lumbar incision is made high and carried far enough forward, plenty of room is obtained, so that the cyst-wall can be readily drawn up into the loin-wound.

Drainage and antiseptic irrigation are effected by means of a large rubber tube, which should be fixed in the cyst, and Condy's fluid, or thymol or weak carbolic acid in solution, should be passed through it daily.

This practice has been very successful, and ought certainly to be adopted when aspiration fails and before nephrectomy is dreamt of.

After nephrotomy has been performed, search should be made with a sound or long probe for a calculus or other foreign body obstructing the renal pelvis or the upper end of the ureter.

Lumbar nephrotomy may be recommended when a fistula in the loin is permanent and there is little or no secreting structure left.

PYO-NEPHROSIS.

Definition.—By pyo-nephrosis is understood dilatation of the pelvis and calyces of the kidney with pus, or pus and urine. It is a mechanical result of obstruction, and something more. It is hydro-nephrosis with pyelitis superadded. Sometimes the amount of pus is so small, the pyelitis so slight, and the amount of pent-up urine so large, that the tumor is called hydro-nephrosis rather than pyo-nephrosis, in spite of the presence of pus. But in all cases where there is suppuration as well as dilatation of the pelvis and calyces of the kidney, the condition is, strictly speaking, pyo-nephrosis.

In advanced cases the dilatation and suppuration extend beyond the calyces and go on to the compression, atrophy, and breaking down of the medullary and cortical substance, until at length the whole kidney is converted into a large and loculated sac. This sac contains pus or purulent urine, or urine mixed with muco-pus in larger or smaller quantity, or pus and urine mixed with blood or with a white phosphatic deposit or mortary paste of phosphate of lime, or débris of renal calculi, according to the cause of obstruction.

Etiology.—Hydro-nephrosis becomes pyo-nephrosis when pyelitis is superadded. The causes which produce hydro-nephrosis produce also pyo-nephrosis. But when an obstruction at once excites pyo-nephrosis it is more complete and irritative in its effects upon the kidney than those which give rise to hydro-nephrosis.

In some cases the pyo-nephrosis has been preceded by pyelitis, the distention being excited by the same cause, but at a later date. Pyelitis followed by pyo-nephrosis sometimes results from wounds and contusions in the renal region.

Pathological Anatomy.—The mucous membrane of the renal pelvis by degrees assumes a dull-white color, very different from the bluish-white semi-transparent color of health, is markedly thickened, and secretes a quantity of pus. The pent-up urine soon becomes alkaline from admixture with the pus, the urea is converted into carbonate of ammonium, and calculous material is often deposited upon the lining membrane of the organ. The thickening of the mucous membrane is sometimes so marked, and the dilatation and distention of the calyces and pelvis so considerable, that the orifices whereby the pouch-like dilatations of the calyces communicate with the pelvis become excessively narrow, occasionally altogether closed by fibrous dissepiments or partitions. As the distention of the cavity of the kidney proceeds, the pyramids and then the cortex of the kidney become more and more atrophied, until at length all the glandular tissue is completely removed and the organ is transformed into a many-chambered cyst, the departments of which open into the dilated pelvis.

Ulceration of the cyst-wall or suppurating tracks formed through what remains of the renal substance sometimes end in fistulous openings into the parts around,—it may be into the cellular tissue of the loin, or into the stomach, duodenum, colon, or peritoneum. Sometimes only one, sometimes several fistulous openings occur in the same case. As soon as a fistula forms, the purulent urine escapes, and gives rise, according to circumstances, to perinephritis, peritonitis, or the discharge of pus and urine by the mouth or rectum or through the loin.

Symptoms.—In the early stages the symptoms of pyo-nephrosis will be those excited by the cause of the obstruction, whatever that may be, and, in addition, those of pyelitis. If the obstruction is not complete there will be pus in the urine; if complete, but intermittent, there will be intervals when no pus is discharged; whilst if the obstruction is both complete and permanent there will be an entire absence of pus in the urine. The urine should, therefore, be carefully and frequently examined, as to both quantity and quality, in each of which it may vary from time to time a good deal. The urine may decompose in the renal pelvis and become alkaline and glairy, as it does in cystitis, but when mixed with the urine from the opposite kidney these characters are so moderated that the urine is usually faintly acid when voided.

There will be constitutional symptoms of suppuration; sometimes shivering, sometimes a high temperature at night without rigors; emaciation, great prostration of strength, loss of appetite, perhaps sickness and diarrhœa, and often a dusky pallor or sallow tinge of skin. When pyo-nephrosis becomes chronic, hectic may supervene. The tumor caused by pyo-nephrosis varies in different cases as to size and other characters, just as it does in hydro-nephrosis.

The pain experienced depends greatly on the size of the tumor: there are in some cases paroxysms of great severity. Pressure over the front of the tumor nearly always aggravates pain, or provokes it if it was not present before. Pressure over the flank, in some cases, is not only well borne, but actually gives relief.

If the opposite kidney is useless, death from anuria may occur. Anuria has been known to result from obstruction of one kidney alone.

Diagnosis.—The tumor caused by pyo-nephrosis will be diagnosed in the same way as that of hydro-nephrosis; and, as pyo-nephrosis is nearly always preceded and accompanied by febrile symptoms, by rigors, and by the presence of pus in the urine in varying amount, we are enabled thereby to distinguish pyo-nephrosis from hydro-nephrosis.

From perinephric abscess the tumor will be made out in the same way as in hydro-nephrosis; but the feverishness and other constitutional signs of suppuration make pyo-nephrosis more likely than hydro-nephrosis to be mistaken for perinephric abscess.

Prognosis.—When due to a removable cause and confined to one kidney the prognosis as regards life is not unfavorable, if early relief to pent-up urine and pus is obtained, either by the restoration of the passage along the ureter or by lumbar incision. When the tumor continues to increase, death will be caused by pressure-effects or by its bursting into some important cavity or organ. When it opens on the surface of the body or into the bowel, recovery may take place, but death from blood-poisoning, hectic, or exhaustion is probable. The most favorable result is when the obstruction ceases and the contents of the tumor discharge along the ureter. Sometimes after the tumor subsides pus is passed in the urine for very long periods or even for the rest of life.

Treatment.—In the early stages the treatment is directed to the removal of the obstruction and the improvement of the pyelitis. Even when a tumor is formed, palliative treatment is permissible when there is not complete obstruction and the pus and urine can escape by the ureter; when there is neither fever, hectic, diarrhœa, emaciation, nor pain, and the tumor is not of such a size as to threaten rupture; when the tumor, from having been of large size, has diminished by the emptying of the cyst along the ureter into the bladder; when the surrounding organs and tissues are not excited to inflammation; and when the age of the patient, or some serious complication of bladder or other organ, renders any operation a danger in itself.

Under these circumstances we shall help to diminish the suppuration, and prevent the occurrence of acute inflammatory action in the cyst, by rest in bed or on the couch, frequent hot baths, anodyne and emollient applications to the loin and abdominal walls, gentle compression by belladonna plasters, the avoidance of constipation and of the accumulation of fæcal matter in the colon and cæcum, and by a light digestible diet, properly regulated according to the constitution of the patient.

If a calculus be impacted in the ureter, an attempt in a very serious case should be made to extract it, either through the bladder or by abdominal section. Or friction over or manipulation of the tumor and adjacent parts might be tried. If the parts are very painful, friction must be tried only under chloroform; and it is not free from danger through increasing inflammation or rupturing the cyst.

In many instances, however, the only proper treatment is nephrotomy, palliatives being useless, and delay in operating dangerous. The circumstances which indicate nephrotomy are constant pain, increasing size of the tumor, continued fever and evening elevations of temperature, serious interference with the functions of the stomach and intestine by reflex irritation or direct pressure of the tumor; when the surrounding structures are inflamed or becoming adherent to the tumor, and when the tumor threatens to rupture or ulcerate into them.

As the several calyces may be shut off from one another, each suppurating cavity should be opened, either by the knife or by the finger, and search should at the same time be made for renal calculus in the pelvis or impacted in the upper end of the ureter.

Lumbar nephrectomy will have to be considered if, after opening and draining the cyst, free suppuration continues, or fresh abscesses within or around the kidney occur and do not permit of thorough drainage through the loin.

RENAL CALCULUS.

Definition.—There is but a step between the formation of gravel and of stone in the kidney. If the solid substances which are usually in a state of solution in the urine become excessive, so as to be deposited as crystals, and if these crystals are carried out of the system with the urine, we have the condition of gravel. If these crystalline forms are cemented together by a little mucus or blood-clot, and are afterwards added to by fresh depositions from the urine, we have a small calculus, which may either be passed off with the urine, causing more or less renal colic in its transit along the ureter, or may remain behind in one of the calyces or in the pelvis of the kidney, there to grow by fresh accretion until it attains a size altogether in excess of anything which can pass along the ureter.

Etiology.—Renal calculus may originate in the deposit of some of the urine-salts around a blood-clot in the renal pelvis, the result of an injury. More frequently it results from a precipitation of some of the solids of the urine which are in excess of the normal amount, this excess, as a rule, being dependent on an error of diet, imperfect digestion, or defective nutrition. Sometimes it is excited by the presence of a sarcomatous or papillomatous growth in the kidney. Renal calculi are formed at all periods of life from the latter weeks of intra-uterine life onward. They are very common in the children of the poor up to the age of fifteen years. The majority of the sufferers from stone in the kidney among the poorer classes are children. It is a rare disease among the children of the well-to-do. The absence of milk and the use of indigestible articles of food in the diet of the children of the poor is probably the cause of the prevalence of renal calculus among them.

Calculus may form in the uriniferous tubes or calyces of the kidney, but it generally grows into importance after it has reached the calyces or pelvis.

The most common form of renal calculus is the uric acid, the next most common is the oxalate of lime. These substances, being but sparingly soluble, are the most likely to be precipitated from the urine; but carbonate of lime, phosphate of lime, a mixture of phosphate and the ammonio-magnesian phosphate (that is, the fusible calculus), cystine, xanthine, and finally urate of ammonium, or the mixed urates, are found occasionally, though rarely, either as the nucleus or chief constituent of renal stones. Alternating calculi of uric acid, oxalate of lime, and phosphates in distinct layers are not uncommon. Blood calculi have been described, and a drop of dried blood is occasionally found as the nucleus of a mixed calculus.

The nucleus of calculi formed in infancy is generally urate of ammonium; at puberty and in young adults it is uric acid; but uric acid, oxalate of lime, and triple phosphate of lime occasionally form the substance of calculi in children.

Pathological Anatomy.—One single calculus or many hundreds may be formed in the same kidney. When there are many, they are scattered throughout the organ, sometimes as grit studding the tissue, and sometimes in nests or excavated spaces in the tubular substance. When single, the size and shape of the stone vary from a small smooth body facetted or rounded, to a large, branched, rough mass filling all the pelvis and calyces.

A stone as large as a marble, rough and sharply mammillated upon its surface, may remain confined to one of the calyces for years without giving rise to more change than induration of the whole organ, due to slight chronic interstitial inflammation. On the other hand, quite a minute stone, not much, if any, larger than a mustard-seed or grape-seed, whilst in the tubular structure of the kidney will excite congestion and even acute inflammation and abscess.

When a stone is of such large size that it fills the renal pelvis, or when, being much smaller, it falls like a ball-valve into the upper end of the ureter, it leads to chronic inflammation, to dilatation, and to those atrophic changes which accompany hydro-nephrosis and pyo-nephrosis; or nephritis, pyelo-nephritis, abscess in the perinephric tissues, or profuse suppuration within the kidney may be the result.

Symptoms.—Renal stones of small size may pass out of the body in considerable numbers without giving rise to more than slight lumbar pains. A moderate-sized and even a large stone may exist for years without revealing its presence at all, or, after having for a time caused symptoms, may for the rest of a long life remain dormant.

As a rule, there is, at some time, blood or albumen mixed with the urine, lumbar pain or aching, aggravated by exercise or by any jolting movement, vesical irritability, or perhaps pain in the testicle of the same side. If the stone has existed a long while, pus, mucus, or albumen will be found daily in minute or moderate or marked quantity in the urine; or if blood is not always present (and in many cases it is not) it may recur from time to time in large amount, making the water bright red or porter-like in color for several days together. If with these symptoms the patient occasionally passes gravel or minute calculi or fragments of calculous matter, the diagnosis becomes conclusive.

Movements such as those caused by carriage-exercise, running, or walking, are not in all cases needed to excite exacerbation of the lumbar pain; on merely turning in bed, or even when lying asleep, the patient may be aroused by a sudden agonizing seizure.

It would thus seem that the varying pressure of the abdominal viscera, the passage of fæces along the colon, the variations in the degree of intra-renal blood-pressure, are all capable of exciting pain by making the renal tissue press against the often angular surface of the calculus. As soon as a stone enters the ureter, or is being propelled along it, stretching it as it goes, renal colic sets in. The attacks of renal colic come on suddenly, last for two or three hours or as many days, and almost as suddenly subside, to recur at some future period, if the stone, instead of escaping at the lower end of the ureter, is simply displaced from the upper orifice into some less important point in the renal pelvis. Recurring attacks of colic arise from fresh formation of renal calculus.

Periodic attacks of renal colic occur in some cases without being followed by the discharge of a calculus or a fragment of a calculus. They are then due to the irritation of a movable calculus in the pelvis of the kidney, or to the passage of a lump of mucus or blood along the ureter. They are more prone to occur or to be most severe when the patient is in low health or over-fatigued.

During these attacks the pain shoots along the branches of the lumbar plexus, and is felt in the bladder, in the groin, along the thigh, or in the testicle. The pain is paroxysmal, and intensified by the spasmodic contractions of the ureter. The testicle may be retracted at the time, and afterwards become enlarged and remain for a long while tender, if not painful. I have seen the testis of the affected side small and wasted as well as retracted. Children may be thrown into convulsions during the fearful agony of renal colic. The attack is often ushered in with a rigor, and is generally accompanied by vomiting, retching, and profuse perspiration. Faintness and collapse are by no means rare. The bladder is irritable, and the urine, which is diminished in quantity during the attack, is blood-stained and loaded with urates, and is sometimes passed with a good deal of scalding in the urethra. It sometimes happens that the other kidney becomes excited to increased secretion during the attack, and then the urine will not be diminished in quantity, and will not be thick.

Apart from the attacks of renal colic, constant or paroxysmal lumbar and renal pain is a very common symptom of a stone in the kidney.

Owing to the wide nerve-connections of the kidney, the pain of renal calculus is often transferred to a distance,—*e.g.*, to the testes along the spermatic plexus and the genito-crural, to the upper part of the thigh by the genito-crural, to the leg and inside of the foot through the anterior crural.

A stone in one kidney sometimes excites pain and irritation in the other. This transferred or sympathetic pain is of an aching character, not often of a colicky nature.

Another symptom which results from transference of nerve-influence has reference to the stomach: nausea, vomiting, and dyspepsia are very common, not only at the times of actual colic, but also during the periods of less acute suffering, being due to the connection of the pneumogastric with the renal plexus. The retraction of the testicle, irritability of the bladder, pain referred to the thorax and sometimes thought to be due to pleurisy, are all explained in the same manner as the gastric disturbance and the pains in the lower limb,—namely, by transference of nerve-influence.

When the patient is very thin, and the stone large, it can sometimes be detected on palpation of the loin, especially when the patient is under the influence of chloroform.

Other common symptoms of renal calculus are hæmaturia and pus in the urine. These vary much in frequency and amount. As a rule, oxalate-of-lime calculi cause most bleeding, phosphatic calculi most suppuration. Lateral inclination of the body and flexion of the thigh are not unusual.

Diagnosis.—Undue acidity of urine and strumous disease of the kidney are the two conditions in children which are most likely to be mistaken for renal calculus. Renal tumors, intestinal colic, and perityphlitis have also occasionally given rise to errors in diagnosis.

Acidity of urine and excess of uric acid in the urine will be removed by alkaline treatment and precautions in diet; there may be frequency of micturition, tenderness of the testicles, and even hæmaturia, but renal colic does not occur, and the lumbar pain or aching is equally on both sides.

Strumous kidney must be suspected when frequency of micturition and slightly purulent urine occur in children of strumous habit or parentage. The absence of hæmaturia makes this diagnosis more, rather than less, certain. Frequency of micturition, with pus and hæmaturia and sharp lumbar or testicular pain, in a healthy child, is almost certainly due to calculus. Struma and calculus sometimes affect the same organ.

From intestinal colic and perityphlitis renal calculus can be distinguished by the localized pain in the loin, the hæmaturia and pus in the urine, the absence of fever, the frequency of micturition, and the testicular pain.

From carcinoma or sarcoma of the kidney calculus may generally be diagnosed by the absence of tumor and the longer duration of the symptoms before the general health of the patient becomes deteriorated. The irregular shape of the tumors and the frequency with which they extend down into the false pelvis serve to distinguish these new growths from calculous hydro-nephrosis and pyo-nephrosis.

Treatment.—The treatment of renal calculus may be considered under three heads: (1) prophylactic; (2) palliative; and (3) surgical.

Prophylaxis consists in employing a *moderate amount* of well-selected food, so as to preserve the digestive and assimilative functions in good order. Animal diet is not harmful if taken in moderation, nor is abstinence from animal diet any security against calculus, as is proved by the prevalence of this disorder among the very poor, who scarcely taste meat.

Palliative treatment consists in the free use of alkaline drinks or distilled water; in the administration of acetate of potassium, carbonate of lithium, citrate of potassium, or carbonate of lime, and of saline aperients, such as sulphate of sodium, sulphate of magnesium, and tartrate of potassium and sodium. The natural mineral waters of Vichy, Ems, Carlsbad, Püllna, and Friedrichshall are advantageous; and with an undue disposition to the formation of uric acid the alkali mineral water of Fachingen is the best. During an attack of pain, confinement to bed, hot baths and anodyne fomentations, and anodynes internally, are the treatment.

Surgical Treatment.—The treatment by operation of the worst pathological consequences of renal calculus have been considered under pyonephrosis and perinephric abscess. Nephrectomy will very rarely be justified for calculus uncomplicated by abscess and disorganization of kidney.

Nephrolithotomy should be performed when symptoms of stone are severe and are not removed or rendered bearable by several months of medicinal treatment and rest, when the patient is compelled to pass his days as well as nights in bed, or when anuria supervenes upon symptoms of calculus in one or both kidneys. In the latter case (*i.e.*, when both kidneys are affected) the kidney which has last become affected should be first explored.

The symptoms which are sufficiently characteristic of stone in the kidney to justify an exploration of the kidney in search for the stone are a history of hæmaturia, the presence of a little pus or of crystals in the urine, together with fixed or more or less constant pain in one loin, groin, or testicle, the pain being either of a dull aching or sharp pricking kind, paroxysmal, and occasionally associated with the other symptoms.

When a fistula leading down to a calculus opens on the surface, all that may be requisite to extract the stone is simply to enlarge the opening and seize it with a proper pair of forceps. When a retroperitoneal abscess is present the stone will probably be detected at once on opening the abscess from the loin. In either of these cases the calculus very probably will be found lying outside the kidney, from which it has escaped by ulceration.

TUBERCULAR AND SCROFULOUS KIDNEY.

Of twenty-eight children under twelve years of age, nineteen had both kidneys affected, five the right only, and four the left only.

Two forms of tubercle (so called) of the kidney are met with: (1) disseminated tuberculosis, and (2) strumous pyelitis, or scrofulous pyelonephritis.

These diseases are more common in children and below the age of puberty than in adult life; but they may occur, and more especially the scrofulous form of the affection, at any age. Males are said to be more frequently affected than females. Both kidneys are rarely involved in an equal degree, and the "scrofulous" form often affects one kidney only.

History and Pathology.—Miliary tuberculosis affects children under ten years of age in a much larger proportion of cases than the scrofulous caseous variety. Miliary tuberculosis generally affects both kidneys. The kidney is affected as part of a general constitutional disease. The miliary nodules begin as gray granulations around the terminal branches of the arterioles which lie between the pyramids of Ferrein. They infiltrate the vascular and connective tissues, and flatten the uriniferous tubes between which they occur. They are seen on the surface as small white dots, and extend along the pyramids of the medulla, having a great tendency to spread downward along the submucous connective tissue to the ureter and bladder, and to involve also the vesiculæ seminales, prostate, and testes.

Scrofulous kidney is known also as strumous pyelitis, scrofulous pyelonephritis, and the inflammatory form of tubercular disease of the kidney. Masses of cheesy infiltration commence in the substance of the renal papillæ, and extend deeply into the kidney as well as downward to the submucous tissue in the renal pelvis. The body of the kidney is enlarged, lobulated by the extension of cheesy infiltration into the cortical parts of the organ, and on section conical masses of this cheesy material in different stages of softening are found to correspond to the prominences of the lobules. The mucous membrane of the renal pelvis and ureter is thickened and at a later period ulcerated and choked up by the putty-like material which exudes. The whole organ may be converted into a huge abscess-cavity or a series of large irregular abscesses. Scrofulous disease sometimes spreads by contact and involves the liver or the spleen.

Symptoms.—*Disseminated tuberculosis* of the kidney produces no characteristic symptoms referable to that organ. In the early stages of *strumous pyelitis* the constitutional symptoms are not marked, and the local symptoms are absent. As the disease advances there is pain in the loin, with tenderness on pressure in the lumbar region. The urine may not be altered in quantity or character; or it may be excessive in quantity, in the early stage; and albuminous, alkaline, or acid, sometimes bloody, or containing pus, minute cheesy masses, and débris of renal tissue, in the later stages. When it contains albumen the urine is always thick, cloudy, or opaque, and not clear, as in Bright's disease; moreover, it never contains casts of the renal tubes. Occasionally there is suppression of urine, more or less complete, and then uræmic symptoms usher in the fatal termination. Often a tumor can be felt, or there is a greatly-increased area of renal dulness; and if the disease be on the left side, the spleen may be so much pushed forward as at first sight to give the impression that the tumor is an enlargement of that organ. I have seen this mistake committed more than once.

Vesical irritation and frequent and painful micturition are common and often the most prominent symptoms. In the advanced stages rigors, exhausting sweats, and finally hectic occur.

Diagnosis.—Unless a tumor exists, or the characteristic cheesy débris is detected in the urine, it is difficult, if not impossible, by the symptoms alone to distinguish scrofulous disease from pyelitis or pyelo-nephritis from any other cause. In the early stage of the disease the diagnosis from renal calculus must depend chiefly on the physical and constitutional signs of tubercle or scrofula. Often a deposit in the epididymis coexists and determines the diagnosis. In stone there is more hæmaturia and less pyuria; in scrofula there is more pyuria and less hæmaturia. The tubercle-bacillus has been discovered in the urine, and should be looked for.

Prognosis.—This is most unfavorable, and the tubercular affection terminates rapidly. The scrofulous form lasts from a few months to a year or more.

Treatment.—This consists in alleviating pain and anodynes locally and internally, tonics, cod-liver oil, maltine, and bland nutritious food. When pus is pent up either in the kidney or behind it, it should be drained away through an opening in the loin. Nephrectomy would be useless in tubercular disease, but promises much as a means of prolonging life in scrofulous affection of one kidney alone. In most instances it should be made a subsequent operation to nephrotomy and drainage; but if the strength of the patient would bear the greater operation, and if from the enlarged size and bossed or nodulated surface of the kidney there was reason to think that the caseous nodules were numerous and large, it would be best to perform nephrectomy at once. To cut into one of several abscess-spaces and to drain it, leaving others unable to discharge their contents, is unsatisfactory in theory and unsuccessful in practice.

The surgeon must, however, bear in mind that it is in scrofulous diseases especially that the probability of the second kidney being likewise diseased is so great; and he must be on his guard against the catastrophe of removing a kidney and losing his patient within a few hours from uræmia due to the destruction of the opposite organ. The chances of such a calamity are much greater when operating on children than on adults, because of the much greater frequency with which both organs are involved in the scrofulous disease in the young than in those past puberty.

SOLID TUMORS OF THE KIDNEY.

The solid growths which occur and present themselves as abdominal tumors in the kidney are carcinoma, sarcoma, fibro-fatty (a variety of small-celled) sarcoma, fibro-sarcoma, myo-sarcoma, and lipoma. Other forms of new growth are met with, but have a general rather than a local importance, and, not giving rise to tumors, will not be here considered.

Definition.—Malignant renal growths—cancer and sarcoma—may be primary or secondary; but, as the latter growths pass undetected during life and are quite insignificant as compared with the disease to which they are secondary, no further reference to them is required here.

The primary growths usually affect one kidney only, attain considerable—often immense—size, grow rapidly, and destroy life by their own local progress. They are far more often sarcomatous than cancerous.

They occur at two periods of life,—namely, in early childhood and in advanced age. The frequency of sarcomatous tumors in early life is consistent with what is known of tumors of connective-tissue origin in other parts of the body, whereas cancerous growths, being of epithelial type, affect most commonly persons of adult and advanced age.

Pathology.—These primary renal tumors of childhood, whether sarcomatous or cancerous, are exceedingly soft in structure and luxuriant in growth. They have been known to reach sixteen or seventeen pounds in weight in six months in children under five years of age; and in a boy in the Middlesex Hospital the tumor weighed thirty-one pounds, the total weight of the child and tumor together being one hundred and thirty-one pounds. Eight or nine pounds is a very common weight for such tumors. Their soft consistence has sometimes led to a renal sarcoma being mistaken during life for ascites.

Primary malignant growths, except the myo-sarcoma, are never bilateral; in the rare instances in which both kidneys have been involved the one is secondarily so to the other. They originate in two situations,—the fibrous stroma of the cortex and the submucous cellular tissue. Sometimes the renal tissue is invaded by a growth which has had its primary seat in the lymphatic glands or other structure about the hilum, or has begun in the renal tissue of the hilum and spread between gland and pelvis, and after penetrating and expanding the capsule has taken on the form of the kidney. Possibly this latter is the commonest mode of origin in primary renal tumors, and explains why the renal pelvis and proper renal tissue remain long intact and why there is such frequent absence of diseased products in the urine. This mode of origin explains, too, how in many cases an enormous tumor involves and effaces only a part of the kidney, leaving the rest of the organ of natural size and appearance and either situated on the outer surface of the growth or more or less surrounded by it. When the disease commences within the renal capsule it infiltrates the organ very rapidly, and cysts with bloody or purulent collections form within it as the disease advances.

These tumors give rise to secondary growths in other organs by invading the venous and lymphatic channels. The lumbar glands are early involved, then the thoracic duct and venous canals, and by extension the lungs, and later on the liver, bones, periosteum, etc. The opposite kidney, as well as the spinal column and cord, is invaded by contiguity.

All forms of cancer of the kidney are met with, but encephaloid is the most usual and attains the largest size. In some instances the growth is encapsuled.

The sarcomas are usually small and large round-celled varieties, sometimes encapsulated, but more frequently not; they are very vascular, and extravasations, often so extensive as to make the whole look like a mass of blood-clot, frequently take place into them. Spindle-celled sarcoma is less common. The so-called fibrous and fibro-fatty tumors are varieties of sarcoma, the latter having undergone extensive fatty degeneration.

Rhabdo-myoma and *myo-sarcoma*, composed of striped muscle and sarcoma tissue, are of congenital origin, and lead to the death of the infant in from six to eight months. In some instances there has been a tumor of each kidney; in some no vestige of normal kidney-structure has remained; in others the tumor has been placed beneath the capsule, but upon the surface of the renal tissue.

Etiology.—Renal calculus and injury and the irritation of pyelitis or retention of urine are the most frequent exciting causes. In many cases in children no cause can be attributed. Sometimes a malignant growth is engrafted upon a serous renal cyst.

Symptoms.—No distinction can be made between the symptoms of cancerous and those of sarcomatous growths. These symptoms are tumor, pain, hæmaturia, emaciation, loss of strength, irritability of bladder, sallowness of skin, and the effects of pressure upon surrounding organs, such as œdema, constipation, vomiting, jaundice, dyspnœa, and interference with the action of the heart. Uræmia is rarely, if ever, a symptom. The existence of a tumor is the most constant sign, and in children this may fill the whole abdomen, but in other cases deep manipulation of the abdomen, assisted by chloroform to relax the parietal muscles, is needed to make out the swelling. Small tumors in children are felt sometimes by the bimanual method. Renal tumors cause fulness, and when of large size bulge laterally; and, though they do not protrude in the loin, they give rise to fulness, resistance, and roundness in the ilio-costal interval which are obvious to eye and touch. In slighter cases they merely efface the hollow of the loin without producing fulness.

They have bowel in front of them with only the rarest exceptions. The colon is almost never absent from the front of a renal tumor, the ascending colon being in front and towards the inner side of a right renal growth, the descending colon in front of a left. Coils of small bowel also are apt to overlie the front of a tumor of either kidney; but when of very great size, so that they are widely in contact with the abdominal walls, the small intestine may be altogether displaced from off the front of the swelling. The duodenum is usually to the upper and left side of a right renal tumor. An exception to the rule that kidney-tumors have bowel in front of them is when the right colon (which is more loosely connected with the right kidney than the left colon is with the left kidney) is pushed down by the tumor, which then advances between the liver and the ascending colon. Another exception is when the renal tumor carries the colon inward towards or beyond the median line.

Renal as well as hepatic and splenic tumors descend with inspiration.

Malignant growths often spring from or attach themselves to some single part of the kidney, and thus the tumor does not retain the original shape of the organ.

Next to swelling, pain is the most constant symptom of malignant disease of the kidney. The harder the growth the more severe the pain: hence children with very soft growths often seem to be entirely free from it. The pain differs from that due to stone in not being intensified by movements, and in less frequently taking the course of the ureter and testicle. It often extends, when the growth is spreading towards the spinal column, to the lower dorsal and lumbar regions and thence down the thighs. Paralysis of the bladder, sphincter ani, and lower limbs, and bed-sores, are later sequelæ of this direction of growth.

Hæmaturia occurs in a considerable minority of cases; but in some of these it has been, no doubt, due to the stone which has excited the new growth. When it is caused by ulceration of the tumor into the renal pelvis the bleeding is continuous and constant, not intermittent. It may be profuse enough to cause anæmia and even death. The urine is of a tawny-brown color, with a bloody, powdery sediment; the blood is uniformly mixed with it, and the urine is not more loaded with blood at the end of each micturition. The hæmaturia differs from that of renal calculus in not being diminished by rest in bed for days together. When not admixed with blood the urine is, as a very general rule, quite natural, containing no casts, no pus, and no cancer-cells. The growth may soften and break down after ulcerating into the colon, duodenum, or ureter, or through the peritoneum or abdominal wall. When either of these events happens, death very quickly follows.

Prognosis.—The disease is always fatal, and more rapidly so in children than in adults. The large majority terminate within six months; the rest usually within the first year. Death has been known to occur within six weeks. The softer the growth the quicker the rate of growth and the earlier the end.

Diagnosis.—The diagnosis has to be made first as to the seat of the tumor; secondly, as to its malignant nature. Attention to the symptoms mentioned above will serve to establish both these points. The initial situation of the swelling, the direction of increase, and the area of dulness on percussion will help to fix the renal origin as distinct from the liver, spleen, or ovary. Errors in this respect are, however, sometimes quite unavoidable. The rapidity of growth and the unequal resistance of the tumor, its nodular outline, and the progressively cachectic condition of the patient, especially if under five or six years of age, indicate with sufficient clearness the malignant nature of the disease.

Treatment.—This is either operative or palliative. Palliative treatment must be thought of only in the middle and later stages of the disease. In the very early stage, when the tumor is small and the lymphatic glands and surrounding parts uninvolved, nephrectomy seems to offer a prospect of prolonging life, and in exceptional cases of securing a permanent cure.

The palliative treatment aims only at relieving pain and checking hemorrhage. Morphine or opium, applied locally and injected subcutaneously or taken by the mouth, will often be required to be used systematically. An ice-bag applied over the tumor gives relief from the burning sensation and the feeling of stretching and bursting often complained of, especially when the increase in growth is rapid. Belladonna plasters and conium poultices afford some degree of relief. Hemorrhage may be sometimes completely arrested by the internal use of gallic acid and ergot combined, by the tannate of aluminium, or by a mixture containing one or two grains or more, according to the age of the patient, of iron alum. The latter drug is specially useful in checking the hemorrhage and the anæmia which goes with it. It is much more effective in bleeding from the kidneys than alum, which is given to children for this purpose in two-grain doses, either as a mixture or with honey or molasses.

CYSTS OF THE KIDNEY.

Definition.—Cysts within the kidney-tissue and those involving the kidney from without are to be distinguished from hydro-nephrosis, which is a cystiform dilatation of the natural cavity of the organ.

There are only three forms of cysts connected with the kidneys of children,—namely, (*a*) congenital cystic metamorphosis of the kidneys; (*b*) paranephric cysts; and (*c*) hydatid cysts. The large solitary cysts which occur in the otherwise healthy kidneys, and which form such striking and often immense tumors in adults, are not met with in the organs of children.

Pathology.—(*a*) Congenital cystic metamorphosis of the kidneys is a fœtal condition, the result of obstruction. It is of more interest to the pathologist than to the surgeon. It is similar to the cystic transformation of adult and advanced extra-uterine life, which gives rise to a tumor on each side and to hæmaturia, uræmia, and the characters of urine like those belonging to granular kidney. Like the extra-uterine disease, the intra-uterine is composed of cysts consisting of dilated and intersected tubes containing urinary matters. The fœtal transformation is associated generally with absence of ureters or pelves, or occlusion of other parts of the excretory passages, such as closure of the straight tubes from impaction of uric acid and from intra-uterine nephritis. There are, too, very often associated malformations of other parts of the body, such as club-foot, hernia cerebri, cleft palate, hare-lip, ectropion vesicæ, supernumerary and webbed fingers and toes, etc. The usual consequence of this transformation is the death and expulsion of the fœtus; or the abdominal swelling due to the kidneys may be so extreme as to prevent the expulsion until after embryotomy has been performed. If premature birth before the death of the fœtus should take place, the child dies soon afterwards, from pulmonary embarrassment or marasmus. When only one organ has been involved, the infant has lived as long as nineteen months, a wretched existence, with symptoms of extreme rickets, exhausted by diarrhœa, and dying at length of uræmia or convulsion. In such cases the kidney is not always large enough to present an abdominal swelling, and the condition has not always been suspected during life, but has been discovered unexpectedly at the post-mortem examination.

(*b*) Paranephric cysts are developed in the perirenal cellulo-fatty tissue, generally posterior to the kidney, with the pelvis or ureter (or both) of which it may communicate. Some of these cysts are congenital, others are due to injury, others, again, are of quite uncertain origin. The attacked kidney is healthy in structure, and the ureter is pervious throughout.

In one recorded case, in a boy aged six years, the cyst held five pints of transparent fluid free from urinary constituents, and there projected into its cavity, from the cyst-wall, at a point five inches from the kidney to which it was attached, a small mass the size of a walnut, which proved to be a perfect single lobule of a third kidney, but without an excretory duct. A prolongation of the cyst passed beneath Poupart's ligament and through the femoral ring.

Diagnosis.—Clinically such cases are indistinguishable from hydronephrosis and from such paranephric cystic formations as occur after injuries to the kidney. They may be mistaken for hydatid of the kidney and for some of the solid renal tumors. They are to be diagnosed from tumors arising in other parts or organs by the same general characters as enable us to diagnose other renal tumors as such. The symptoms excited are merely the same local features and pressure-effects caused by other renal tumors.

Treatment.—Paranephric cysts require to be treated like hydatid cysts and hydro-nephrosis. They should be tapped and emptied with a trocar and canula, and if they refill again and again they should be opened and drained, through either the coni or the side of the abdomen, according to their position, and the edges of the cyst should be stitched to the edges of the wound in the abdominal parietes.

HYDATID OF THE KIDNEY.

Etiology.—Hydatid is the cystic stage of the tænia echinococcus, an intestinal tape-worm common in the dog and the wolf. This tape-worm consists of four segments, and is about the size of a millet-seed. The last segment is the only fertile one, but this contains four or five thousand ova. The ova taken in water or food into the body of man and many other animals there develop into large cystic tumors, which form the largest parasitic growths to which man is subject.

Pathology.—Hydatid cysts grow either in the glandular substance or in the subcapsular cellular tissue of the kidney. The renal substance atrophies in varying degrees, from the pressure exerted by the tumor. Sometimes the whole kidney is destroyed, and the cystic swelling may fill the greater part of the abdominal cavity. Frequently the cyst bursts into the pelvis of the kidney, the ureter, the intestine, or the lung; rarely, if ever, externally. Inflammation and suppuration occasionally attack the cysts; or the tumor may contract and dry up, leaving a putty-like or osseous or cretified mass. Many cysts of different sizes sometimes exist in the same kidney. The left organ is most frequently affected.

Symptoms.—Hydatid is the only parasite which forms a renal tumor. The usual period of the disease is after the twenty-fifth year; but it has been found in the fœtus, and also as an occasional occurrence in infancy and childhood. Some of the adult patients whose histories have been recorded are known to have been affected—indeed, to have voided hydatids from the kidney—since the first, second, third, or fourth year of life. About one-half the cases of hydatid disease of the kidney form tumors appreciable during life. The tumor is usually globular, more or less fills the coni, varies in size from that of an orange to a mass filling the whole abdomen, is elastic to the feel, and sometimes fluctuating. The relation to intestines and other surrounding parts accords with that of renal tumors generally. In the majority of cases of this disease renal hydatids escape with the urine, and in some cases by the bronchi, stomach, or rectum at the same time as by the urinary passages.

A sense of something giving way and pain in the coni and along the ureter usually precede the escape of the vesicles. Rigors, vomiting, spasmodic colicky pain, and sometimes suppression of urine and retraction of the testicle accompany their transit along the ureter, which occupies from a few hours to a few days. Then comes a period of relief during their sojourn in the bladder, followed by painful efforts at micturition and by retention of urine until they have completed their journey through the urethra. Whether they burst, or do not, the hydatid cyst may suppurate. Unlike renal calculus, however, suppuration in connection with hydatids never opens externally nor into the peritoneum. The duration of the disease is quite uncertain, recovery being sometimes perfect after one or two discharges of vesicles, whereas in other cases recurrences of the discharge of vesicles have taken place during twenty, thirty, or more years.

Diagnosis.—There is no difficulty in the diagnosis when with a tumor in the renal region vesicles, hooklets, or pieces of laminated membrane have been voided with the urine,—except that in some few cases these structures have escaped into the renal pelvis or ureter from a tumor not of the kidney itself, but in its immediate neighborhood. When nothing characteristic passes with the urine the diagnosis from cystic or hydro-nephrotic kidney can scarcely be made. Malignant disease will be told by its very rapid growth and the pain and cachexia it causes. When suppuration occurs in the hydatid cyst the fever and other associated constitutional symptoms may suggest pyonephrosis. The colic of renal calculus is simulated when vesicles travel along the ureter, but the diagnosis is determined by the urine. Aspiration and the examination of the fluid removed clinch the diagnosis when hydatid elements are found in it.

Prognosis.—This is generally favorable: in many instances the disease has terminated in cure by the spontaneous evacuation of the cyst-contents; in others, by the withering and drying up of the tumor. When death results it is from suppuration, from suppression of urine, from bronchitis set up by the bursting of the cyst into the bronchi, or from pleurisy or pneumonia due to pressure.

Treatment.—Turpentine, iodide of potassium, and the oil of male fern have each been credited with doing good in particular cases, but probably with doubtful reason. Certainly medicines, if not actually useless, are quite unreliable; though when a communication exists between the hydatid cyst and renal pelvis, beverages containing nitre, alkalies, and some of the vermicide drugs have seemed to stimulate the escape of the vesicles.

When the tumor is of large size without a communication with the ureter or renal pelvis, the proper treatment is to cut down upon the cyst, and, having tapped it and emptied it of its contents, to incise its walls and stretch the cut edges to the margins of the skin-wound. The tumor should be opened from the coni if possible; if not, then at its most prominent point. Aspiration may be tried before incision, but is a far less certain measure.

Owing to the frequency with which these cysts empty themselves through the duct of the kidney, and also to the known improbability of their ever bursting into the peritoneum, there is nothing like the same necessity to evacuate a tumor of the kidney as there is in hydatid of the liver. When the cyst is suppurating and causing much constitutional or local trouble, it should be incised and drained, even though a communication with the renal pelvis has been previously established.

INJURIES OF THE KIDNEY.

Injuries which involve the kidneys are of various kinds. They may be conveniently classed under four heads:

1. Subparietal injuries of the kidney.
2. Those in which an open wound communicates with the injured kidney.
3. Prolapse of the *injured* kidney through an external wound.
4. Prolapse of the *uninjured* kidney through an external wound.

The relative frequency of these several forms of injury is shown by the fact that out of two thousand six hundred and ten inspections of persons dying of all kinds of injuries and diseases, there were thirteen cases of injured kidney; of these, twelve were subparietal injuries and one was a penetrating wound.

SUBPARIETAL INJURIES.—These, being by far the most common, will engage the chief part of the space allotted to the subject of injuries.

Causes.—The causes of subparietal injuries are falls and blows upon the loin, the abdomen, or the lower part of the thorax; the forcible bending of the trunk in falling from a height; and crushes, as in the passage of a carriage-wheel over the belly.

Pathology.—The nature of the injury varies much. Most commonly there is more or less laceration of the renal substance; much less frequently there is complete rupture through the whole organ; rarely the whole kidney is crushed into a pulp; and sometimes, on the other hand, the damage is limited to the outer or inner surface of the organ, so that blood is effused beneath the fibrous capsule or into the pelvis without any distinct rupture of the substance, and the source of the bleeding cannot be made out. In the majority of cases blood is extravasated, sometimes in large quantities, into the circumrenal tissue. Occasionally no hæmaturia and no local swelling follow an injury of the kidney for days or a few weeks, and then, as the result perhaps of walking or moving about, severe hæmaturia or sudden and extensive swelling takes place in the loin and abdomen. The later results of injured kidney are pyo-nephrosis, renal abscess, perinephric abscess, hydro-nephrosis, or maybe some *extra-renal* cystic formation filled with urine mixed, or perhaps not mixed, with blood-clot or pus. In these subparietal wounds very frequently some other viscus besides the kidney is injured at the same time; but often the kidney is the only organ damaged. Occasionally fractured ribs complicate or cause directly the damage to the kidney.

Symptoms.—Hæmaturia following an injury to the loin or the front of the ilio-costal area of the abdomen is not necessarily symptomatic of *ruptured* or *lacerated* kidney; and, on the other hand, hæmaturia is not always a symptom when the kidney is severely lacerated or completely ruptured. If the ureter becomes plugged by clot, so that neither blood nor urine can get down to the bladder from the injured organ, hæmaturia cannot occur, and the kidney may be ultimately lost as an excreting organ. If the cortical substance of the kidney is only superficially lacerated, there need not be even the smallest drop of blood passed with the urine.

1. Hæmaturia may denote simply *contusion of the kidney.*

2. Hæmaturia may arise by simple transudation of blood from a temporarily congested kidney, and without any appreciable breach of surface.

3. When hæmaturia does not occur immediately but only at an interval of some days after an injury, it may be due (*a*) to the displacement of a clot which was formed during the syncope or collapse induced by the injury, or (*b*) to the escape of a clot along the ureter which for a time completely obstructed the passage of urine or blood from the injured organ.

After contusion or laceration of the kidney the quantity of blood passed with the urine during the first few hours sometimes amounts to many ounces. In other cases it is very small in amount at first. In some cases hæmaturia may not appear at all for several days, or, having appeared, may disappear for several days, and then recur on going to stool, or on taking a short ride or drive, or on making some, it may be even slight, muscular effort. Hæmaturia has been absent in cases where the kidney has been completely ruptured in two.

The earliest symptom after the collapse in many cases is pain in the loin or renal area of the abdomen, shooting down perhaps to the testicle, groin, or thigh. Ecchymosis of the loin may or may not be present. The urine may be either partially or entirely suppressed, or simply retained in the bladder. In other cases it is passed naturally. If there are blood-clots in the urine they should be carefully floated out in water and their shape examined: some hint as to the situation of the injury may be acquired thus. There may be severe renal colic from passage of clot along the ureter, or frequent and painful micturition from its presence at the neck of the bladder or in the urethra.

A tumor in the region of the injured kidney is a sign of much importance. In some cases this is formed and rapidly increased in size during the first day or two after the injury; it is then attended with fever, abdominal distention, œdema of the skin of the loin, extreme tenderness, and agonizing pain. In other cases there may be no tumor for many days or weeks, but subsequently a large cystic swelling may develop and not give rise to pain or tenderness until it has attained considerable size.

Prognosis.—Contusions and superficial lacerations of the kidneys are very capable of recovery; but complete rupture is pretty nearly sure to cause death from hemorrhage or peritonitis unless the loin is incised, the hemorrhage checked, and perhaps the kidney removed by operation. If the peritoneum is untorn and the renal artery and vein escape laceration, there is every prospect of recovery from these injuries if properly and promptly treated.

Diagnosis.—After an injury to the kidney or ureter symptoms are sometimes absent, or so obscure and insufficient for several days that no damage to the organ can be made out; but after a longer interval hæmaturia may occur or a tumor may form, and then the nature of the injury is made clear. Experience shows that these are very important facts to bear in mind, and should make us watchful before concluding that the kidney is intact.

If, when the collapse from an abdominal injury has passed off, pain in the hypochondriac or lumbar region continues, and there is vomiting, with anxiety of countenance; if, moreover, the urine contains blood and blood-casts, gradually diminishing in quantity, for from three or four to six or seven days or longer, and if convalescence is slow, the suspicion that some contusion or laceration has occurred is justly aroused.

If after the abdomen has been run over, or the child has fallen or been struck on the abdomen or loin, faintness, coldness, vomiting, and abdominal pain follow; if on the day of or the day after the accident, and whether the catheter be required or not, the urine is found to contain a quantity of blood and blood-clot; and if after several days blood-clots continue to pass, or pus as well as blood is voided in the urine; if, moreover, there is pain along the course of the ureter, with retraction of the testis, or a rigid and prominent state of some of the muscles of one side of the abdomen, with frequent desire to micturate; or, finally, if a tumor, dull on percussion, forms in the loin or in the lumbar or hypochondriac region of the abdomen, accompanied or not with signs of local peritonitis, there are safe grounds for believing that either the kidney or its pelvis has been ruptured.

Treatment.—Absolute rest in bed, the avoidance of stimulants and solid food, and the alleviation of pain and restlessness by anodynes are all indicated. In all cases the diet must be bland in nature, fluid in character, and limited in quantity.

Pain is sometimes assuaged by strapping the affected side of the body, a practice which also tends to limit and check hemorrhage. Caution must be used in acting on the bowels, as hæmaturia is sometimes excited by an aperient or an enema. The internal use of astringents, especially ergot, may be called for to check hemorrhage, but, with the same object, every precaution must be taken against exciting irritability of the stomach; and if vomiting occurs, food as well as medicine must be given solely by the rectum.

In every case where, from the increasing painfulness, tenderness, and œdema of the loin, it is obvious that extravasation of urine or of urine and blood is going on, also where inflammation and suppuration are threatened and the patient's general condition is becoming more and more critical, lumbar incision ought to be resorted to without delay, and the question of nephrectomy decided by the conditions discovered. In most cases, except for profuse and uncontrollable hemorrhage, it will be best at first to rest content with free lumbar incision and drainage, reserving nephrectomy for a future time should the subsequent symptoms indicate it.

If at a later period after the injury hydro-nephrosis, pyo-nephrosis, or a renal or perinephric abscess should result, the treatment should be guided on the same principles as those laid down under these different headings.

In certain cases where the continued passing of blood-clots into the bladder leads to cystitis and the gradual wearing out of the patient by pain and painful micturition and fever, cystotomy should be employed and the clots thus removed; but what is far better is, by early lumbar incision, and, if needful, nephrectomy, to put a stop to the hemorrhage and the painful and frequent micturition which is caused by it, and thus also to prevent the onset of cystitis.

PENETRATING WOUNDS OF THE KIDNEY COMMUNICATING WITH AN EXTERNAL WOUND.—They may be inflicted either from the loin or through the peritoneum. They cause pain extending to the groin and testicle, difficult micturition, and hæmaturia or the discharge of pure blood along the urethra. Possibly, but by no means necessarily, urine may escape through the external wound. These symptoms, together with the situation, depth, and direction of the wound, leave no doubt, in most cases, as to the nature of the injury. Foreign substances, such as pieces of clothing or bone, may be carried into the kidney, and give rise to great suffering while passing along the ureter to the bladder and thence along the urethra. Penetrating wounds are attended and followed by the same general and local symptoms and pathological changes which have been described under subparietal injuries. Obstinate or permanent urinary fistula is not a common sequel of these wounds.

The prognosis of these wounds is not more grave than that of the contusions and lacerations above described. Wounds which communicate with the peritoneum are more serious than those which do not, on account both of the insidious and dangerous hemorrhage, and of the extent and severity of the inflammation which is apt to be set up either by the injury itself or by the extravasation of urine and blood.

The treatment must be directed on the same lines as that for contusions and lacerations when there is no external wound. In no case should a wound in the loin communicating with the kidney be closed, but left open for free drainage. When the wound traverses the peritoneum it will in all probability involve the bowel or some other viscus. Whether it does so or not, a penetrating wound of the peritoneum, unless the patient is too profoundly collapsed, should be treated by laparotomy, any wound in the intestine should be stitched up, and the peritoneal cavity thoroughly cleansed by irrigating with warm water previously boiled. Whether nephrectomy will be advisable or not will depend on the nature of the injury done to the kidney. If either renal artery or vein is wounded, or the kidney is greatly injured, or a large communication exists between the pelvis of the kidney and the peritoneum, it will be necessary to excise the kidney at once.

Where only the surface of the kidney is wounded and the renal pelvis is not opened, there is little, if any, probability of urinary extravasation, and nephrectomy is not indicated. Where the peritoneum communicates with the renal pelvis, or the ureter, through a small puncture, the opening in the viscus should be closed with sutures.

PROLAPSE OF THE KIDNEY THROUGH AN EXTERNAL WOUND.—The kidney may be prolapsed through a wound either in the back, or on the front of the abdomen. When through a posterior wound, the peritoneum need not be injured.

The prolapsed kidney may be either injured or uninjured. The prolapse may take place primarily,—that is, at the time of the infliction of the parietal wound; or secondarily,—that is, some time after the infliction of the wound, as the consequence of coughing, sneezing, or some other considerable muscular effort.

The prolapse may be only partial,—that is, only one end of the kidney may project through the wound, as in the case of a boy, aged fourteen, where the lower end of the right kidney, from which a large piece had been chipped off so as to lay open the cavity of the renal pelvis, projected through a wound just above the crest of the ilium.

The wound through which the prolapsed organ appears may be inflicted by some penetrating or cutting weapon, by a fall, or by gunshot.

When not much injured, the kidney should be replaced if the case is seen before strangulation of the organ has occurred. When the renal artery or vein requires ligaturing, or the organ is considerably pulped or lacerated, the kidney must be removed after ligaturing its pedicle.

If a portion of the prolapsed kidney has been broken off, but the bulk of the organ is not much bruised and the blood-vessels and ureter are intact, the large remnant of kidney should be replaced, with the fair expectation that the wound will close and the damaged organ continue to excrete urine. Such was the case in the boy above referred to, who completely recovered at the end of eight weeks.

ENURESIS—INCONTINENCE OF URINE.

BY A. JACOBI, M.D.

THE incomplete development of the sphincters, in the infant, results in the involuntary emission of urine and discharge of fæces. This condition prevails a year or two, and is not attended with any subjective sensation, or sensitiveness. The sphincter ani is the first to gain sufficient strength to retain the contents of the rectum; debilitating diseases occurring in later years may restore it to its original incompetency. The sphincter of the bladder attains a satisfactory power towards the end of the second year. When, however, its infantile condition persists beyond that period, both the urine and the genito-urinary organs being fairly normal, the involuntary emission of urine continues, particularly during sleep (*enuresis nocturna*), not infrequently through the day (*enuresis diurna*), or both in the night and during the day (*enuresis continua*). Many of such cases get well spontaneously about the period of puberty, when the whole genito-urinary apparatus undergoes a rapid development. In some the functional weakness, however, persists long beyond that time. Not long ago I had to relieve the case of a young lady of eighteen who was getting ready to marry. Most cases are observed between the third and the tenth year in both boys and girls, but the majority of the patients between the eleventh and the thirteenth year, also of those who suffer in more advanced years, are males.

The muscular debility of the neck of the bladder and the internal sphincter (in fact, identical organs) is sometimes but a part of a universal muscular incompetency, which is found among different classes of children. Some are slow, dull, and stupid, and lacking in general innervation; others are simply anæmic, ill developed, and generally feeble; there are some whose whole vitality appears to be expended upon their intellectual sphere: they are smart, quick, spirited, excitable, mentally vigorous though easily exhausted; but their muscles are thin, sensitive, and incontinence of urine is frequent. In many such cases the sexual and urinary organs are quite small. There are others, however, who exhibit no parallelism of debility in the urinary muscular apparatus and the muscle-supply of the whole body. In them there may be great muscular general development, and the neck of the bladder alone seems neglected. On the other hand, there may be great muscular power about the sphincter in an otherwise feeble and anæmic body. Thus, no certain rule can be established, and the diagnosis of the exact condition of things may become quite difficult. Still there is a class of patients in whom the complication of enuresis with general muscular insufficiency is very apparent. Indeed, young men who after moderate venereal excesses suffer much from nocturnal or diurnal seminal emissions (with or without incontinence of urine) are frequently those who have a positive history of incontinence during their childhood. In them the whole muscular apparatus was defective; and the posterior part of the urethra, when narcotized, as it were, during sleep, gives way before the gentlest pressure on the part of the expelling muscle of the bladder.

Insufficient innervation has been alluded to as a cause of incontinence. Children who pass urine while engaged in eager play may suffer either from debility of the sphincter or from want of mental control. Particularly in diseases of the nerve-centres, with sopor and slow mental action, and where the development of the reflex apparatus is slow and defective, the sphincter, which contracts normally while the bladder is filling up, loses its control. Profound sleep is said to promote incontinence; still all children have that profound sleep, and but a small percentage are afflicted with incontinence. Such general constitutional disorders as scrofulosis and rhachitis have been charged with producing incontinence, but the vast majority of scrofulous and rhachitical children do not suffer from it. Slow carbonic-acid poisoning is also credited with resulting in incontinence; thus it is that G. W. Major and Ziem explain the incontinence of mouth-breathing children, and E. Bloch the nervous disposition, restless sleep, and vivid dreams in which the peripherous irritation of the expanded bladder is more readily perceived, thus overcoming the resistance of the sphincter.

Diseases of the spinal cord which lead to incontinence are rare in childhood. Tabes with incontinence accompanied by retention is of the very rarest occurrence; nor is spasm of the urethra, with consecutive dribbling while the spasm is passing, at all frequent.

Nor are local causes leading to partial patency of the orifice of the bladder occurrences which have to be taken into frequent account. Only adult age suffers from asymmetric hypertrophy or atrophy of the prostate gland, from foreign bodies, tubercles, ulcerations, and gangrene in the orifice, from fistula after parturition, from want of contractility after dilatation, and from injury after perineal section. It is true that exceptional cases of the latter kind may occur in the young; but, when they do, their histories are known and their results are easily accounted for. In a few instances I have met with polypoid excrescences at the neck of the bladder of very young girls. The removal of these granulations relieved the incontinence of urine.

While a large number of cases of enuresis are merely the results of the persistence of the infantile weakness of the neck, another series of cases depend on the increased reflex irritability of the bladder, complicated or uncomplicated with the above-described incompetency of the sphincter. That increased reflex irritability may depend on the bladder itself, or may have its source outside.

Expansion of the bladder with urine is a frequent cause of nocturnal incontinence. Hence the drinking of large quantities of water or other beverage in the evening must be prohibited. The effect of the urine contained in the bladder becomes the more injurious the more it is loaded with solid constituents. Urates and phosphates in superabundance are the results of large meals, mainly of nitrogenous material, and inadequate assimilation. The copious use of table-salt, and of salines in general, also of chlorate of potassium or chlorate of sodium, increases diuresis. Polyuria from a cause located in a nerve-centre has the same effect on the bladder, and diabetes mellitus operates by both the large amount of urine and the alterations in its chemical composition. Cystitis in all its forms adds to the irritability of the detrusor: it is a frequent cause of incontinence when this makes its appearance in children whose micturition was normal before. Stone in the bladder has the same effect. Phimosis and tight adhesion of the prepuce may produce incontinence, particularly in those boys who are subject to frequent erections. The rest of the urinary organs exhibit the same influence. Thus in every case of enuresis with uncertain diagnosis nephritis, pyelitis, renal calculus, and vaginal catarrh must be searched for. As a result of incontinence of urine the bladder is apt to be very much contracted: it holds but little, and thus what was originally the result of incontinence becomes an additional cause.

Masturbation is not an uncommon cause of incontinence of urine. I believe that my paper on the subject of masturbation and hysteria in infancy and childhood[1] has directed the attention of the profession to the frequency of the habit of masturbation, with all its consequences. Now, in the young the caput gallinaginis is quite large, and Cowper's glands and the vesiculæ prostaticæ are sufficiently developed to result in erections. The constant irritation of the part by self-abuse leads to a chronic inflammation of the whole prostatic portion and the neck of the bladder, which is very sensitive. Infants addicted to the habit are very apt to escape for years its consequences as exhibited in somewhat advanced children; these suffer from general malaise, dull headaches, alteration of temper, and somnolence. The genital organs are mostly changed. The external parts—the vulva, the scrotum, and particularly the glans penis—are rather enlarged, and the urine is sometimes alkaline, and often slightly opaque with mucus, leucocytes, and spherical and oval epithelia, sometimes even spermatozoa.

The condition of the rectum must be carefully examined in every case. The plexus pudendus controls both it and the neighboring organs; the pudendal, perineal, and middle and inferior hemorrhoidal nerves are distributed over the lower portion of the bladder and the vagina. Thus a rectal irritation produced by the retention of fæces, the presence of a fissure, which is much more frequent in infancy and childhood than is generally supposed, and the effect of worms (mostly oxyuris) in the lower end of the intestinal tract, are among the more common causes of incontinence.

---

[1] American Journal of Obstetrics and Diseases of Women and Children, February and June, 1876.

Serious disorders of the nervous system, such as epilepsy or night-terrors, are also among the causes or complications of incontinence. They, however, and particularly the latter, need not be taken as causes only; in many cases the night-terror is but a result, co-ordinate with incontinence, of some distant, frequently digestive, disorder.

Treatment.—The great variety of the causes of incontinence of urine requires tact and discrimination in the selection of remedies. General anæmia and muscular debility indicate a diet carefully selected for its nutritiousness and digestibility. Gentle massage of the whole body, sponging with alcohol and water (1 : 6) or with water, and efficient friction with thick towels, sea-bathing, and the use of medicinal roborants, such as iron or arsenious acid, will always prove beneficial. The elixir peps. bism. et strychn. of the National Formulary is a good preparation for use in insufficient gastric digestion, with atony of the stomach; a child of three years may take a teaspoonful three times a day.

Attention must be paid to the capacity of the bladder. In every case, particularly in the evening, the quantity of fluid must be restricted. The sigmoid flexure and the rectum must be empty in the night, and patients should be encouraged to evacuate both bladder and rectum before retiring. After a few hours' sleep the children ought to be taken up and roused sufficiently for both purposes.

Muscular debility of the neck of the bladder (sphincter) requires general and local stimulation. Strychnine or other preparations of nux vomica prove effective to a certain extent by improving both the general innervation and the appetite; in desperate cases an occasional subcutaneous injection into the perineum (gr. $\frac{1}{40}-\frac{1}{16}$) has rendered good service; an ointment of one part of extract of nux vomica in from ten to sixteen parts of fat, introduced into the rectum (size of a coffee or Lima bean) several times daily will also act well and can be continued for some time. The same indication is fulfilled by ergot, the fluid or the solid extract of which may be employed internally. The interrupted electrical current is perhaps the most powerful local stimulant; one of the electrodes must be applied to the perineum, the other to the hypogastrium or the lumbar region. The advice to apply the negative pole to the interior of the urethra or bladder and the positive somewhere externally is bad, because of the danger of urethritis and cystitis.

Whenever there is oxalic acid or sugar or an excess of urates and phosphates in the urine, the source of the disturbance must be attended to. The digestive disorders forming the source of the anomalous condition require a corresponding change in the diet (diminution of nitrogenous food) or correction of the functional disorders of the stomach and liver. Until that object can be accomplished the prognosis is very uncertain. Vesical catarrh, nephritis, and the presence of a calculus in either the kidney or the bladder have their own indications; the consideration of which, as they are treated in other parts of this volume, is here omitted. The hyperæsthesia of the body of the bladder, complicated or not with catarrh,—it is often found without it,—requires belladonna or its alkaloid. Both belladonna and atropine are tolerated in much larger doses by children, in proportion to their size or age, than by adults. In many cases a single evening dose of extract of belladonna (gr. $\frac{1}{4}-\frac{3}{4}-1$) or sulphate of atropine (gr. $\frac{1}{100}-\frac{1}{75}$) answers well. sometimes to an unexpected degree. Bromide of potassium (gr. vi–xxv), camphor (gr. ii–v), extract. humuli fluidum (♏ iv–x), or the elixir humuli of the National Formulary in teaspoonful doses, given at bedtime, answer a similar purpose.

Causes of reflex contraction located in the vagina, penis, or rectum require local correction. Vaginal catarrh is as obstinate because of its inaccessibility as it is frequent. Polypoid excrescences about the vagina or in the urethra (of the female) must be removed; if there be phimosis, circumcision is required. But a great many cases which are presented for that purpose could easily be remedied by gentle dilatation of the prepuce. Firm adhesion of the prepuce requires careful detaching. Intestinal worms must be removed, and the fact remembered that oxyuris has its original seat in the upper part of the colon and the lower part of the ileum, so that rectal injections have but a temporary effect in most cases. Fissure of the rectum, mostly of small size and located posteriorly, requires forcible dilatation, a procedure which demands no time and no anæsthetic, but is very efficient.

Irritability of the neck of the bladder and the prostatic part of the urethra has been treated by Henry Thompson with cauterization by means of a two-per-cent. solution of nitrate of silver. A solution of one part in a thousand of distilled water will be found sufficient, or a solution of one or two parts of tannin or alum in a hundred. Still, it is a better plan to introduce either an elastic catheter or a metal sound into the bladder, every few days, for two or four minutes. A few drops of a solution of cocaine instilled into and distributed in the urethra a few minutes before the insertion of the instrument will in many cases render anæsthesia superfluous.

The latter, however, cannot always be dispensed with. In the case of a girl of three years, with chronic catarrh of the bladder and incontinence, anæsthesia was required a dozen times, for two purposes,—first, to inject a solution of nitrate of silver (1 : 1000) into the bladder, and, secondly, to dilate forcibly, with increasing amounts of water, the organ, which had habituated itself not to hold more than a few drachms of fluid at a time.

Masturbation, which is so frequently the cause of irritation of the prostatic portion, has its own indications. Its cure is by no means easy. Infants can be watched and forcible prevention of self-abuse (mostly by the thighs or hands) exercised; but children of more advanced years require an unusual amount of firmness and supervision. Bodily punishment will avail but little; in the treatment of incontinence from whatsoever cause, nothing.

VESICAL, URETHRAL, AND PREPUTIAL CALCULI.

By WILLIAM HUNT, M.D.

Fifty to sixty per cent. of cases of stone in the bladder occur in children under sixteen years of age. Many statistical tables from different authorities attest this fact. Elaborate discussions are gone into by some writers as to the relative liability to stone at different ages,—that is, as to the number of cases that exist compared to the number of persons living at a given age. Thus it appears to be developed that stone is relatively more common after sixty than before twenty; but the absolute and practical fact remains, that as many children come under the hands of the surgeon for relief from this distressing and most painful malady as the combined number of adults suffering from the same cause at all ages of their lives.

From this it might be plausibly maintained that the anatomy of the juvenile genito-urinary organs, the pelvis, and the perineum should hold a larger place in the studies of the lithotomist than that of the fully-developed adult, which is universally taken as the standard. The writer does not remember to have seen the perineum of a boy demonstrated to students. It will be seen, as we go on, that independent of facts as to relative size there are real differences as to position and development which it is necessary for the operator to know and to appreciate.

These statements would also seem strongly to support the opinion that heredity enters largely as a factor in the production of stone. That stone is frequently congenital there is no doubt. Langenbeck found calculus in the bladder of a male fœtus of six months, thus proving its existence in intra-uterine life. Brendel quotes three cases of stone in the bladder found within two days after birth. Jacobi quotes six cases in forty autopsies of very young children, and he plausibly suggests that the obstinate colics of some infants may be renal in character. There is no doubt that this is sometimes the case; and when relief from colic pains is not obtained by ordinary treatment, special investigation should be directed to the kidneys and bladder. Dr. Arthur V. Meigs has in his possession a calculus removed post mortem from the kidney of a child of six months, a foundling who died of marasmus. The kidney was otherwise, both to the naked eye and histologically, healthy. The weight of the stone is one and one-fifth grains; size, seven-thirty-seconds by six-thirty-seconds of an inch. There was another stone nearly if not quite as large, which was lost. From what we know of the growth of stone it is fair to assume that these specimens began during fœtal life.

Dr. E. L. Keyes, of New York (from whose complete monograph on stone in Ashhurst's "Encyclopædia" I now quote), removed from a boy of nine years, by a successful lithotomy, three stones, weighing collectively nearly two ounces, which the mother said had been diagnosticated at the time of birth of the child. Troiski extracted from the urethra of a male infant one month old a uric-acid stone weighing twenty-five centigrammes and measuring eight millimetres long and five millimetres broad. Dr. T. G. Morton had a case of quite large stone in a child of sixteen months. These cases are sufficient to prove how early calculus may appear, and from literature and experience they could be multiplied to an indefinite extent.

Heredity in general may be explained by the fact that many families for generations live under the same conditions of salubrity or insalubrity, as to place, clothing, food and drink, occupation and habits, and these all exercise potent and similar influences on parents and offspring. Keyes suggests that the apparent regional distribution of stone may have something to do with the above influences, and that as means of travel and locomotion become more common, and are more freely used, centres of its formation may be finally broken up, by reason of more mixed marriages disturbing hereditary tendencies.

Many cases of hereditary stone are reported. Cadge gives in the *Lancet*[1] the case of a woman who had calculus, whose father died after an operation, and whose brother was then suffering from stone. A classical case is that of Clubbe, who thus reports it to the *Lancet* of February 10, 1872 (p. 204):

> "There is a man residing in this town, by occupation a fisherman. During the last four or five years I have cut three of his sons for stone, at the respective ages of two, three, and eight. Two of the stones were lithic acid, one apparently lithate of ammonia. The father and mother of these lads always have lithic-acid sediment, often gravel, deposited from their urine. The grandfather passed one stone and the grandmother seven. A great-uncle was cut for stone. There are six uncles and four aunts. They all suffer either from fits of the gravel or from gravelly or sedimentary lithic-acid deposits; and, to finish up with, there is a cousin, an uncle's child, who gets rid of urinary calculi.
>
> "W. H. CLUBBE,
> "*Surgeon of the Lowestoft Infirmary.*
>
> "LOWESTOFT, January 9, 1872."

It is admitted that the urine of infants is richer in uric acid than that of adults. The uric-acid infarctions of Virchow, the urates of sodium and ammonium constituting the grit found in the kidney-tubules of infants, the brown dust on their napkins which is known by the microscope to be mostly formed of uric acid, all point to a congenital or inherited tendency to produce this substance in excess. This excess may be positive or relative,—positive in proportion to all other ingredients, and relative in that other ingredients may be deficient. Thus we can understand the infantile tendency to acid stone, for, while almost any variety of stone may originate in the kidneys, the uric-acid variety, either wholly or as a nucleus, predominates to such an extent as to constitute, according to the best authorities, from two-thirds to five-sixths of all calculi, these authorities taking the nucleus as the most scientific basis of classification. In this view other deposits, except perhaps that of the oxalate of lime, however large in bulk, may be regarded as secondary, the accretions mostly being deposited after the nucleus has descended into the bladder. Thus, uric acid, the urates of sodium and ammonium, and the oxalates constitute most of the beginnings of stone in children as well as in adults. Their bulk may be largely increased by other deposits, notably of the phosphates. Pure or almost pure phosphatic vesical and prostatic stones, there is reason to believe, have their origin in the places where they are found, and they are mostly peculiar to adults.

---

[1] January 5, 1884, p. 6.

A certain amount of cementing matter is necessary to the formation of calculus. The distinction between it and gravel is that the latter preserves its mineral character, while the former is modified both in shape and consistency by the admixture of organic material. These colloids, as they are called, are derived from the albumins and mucus, and exercise most important physiological functions, but, following the law of irritation, they form in excess at the irritating point and make abnormal combinations. The irritant, in the shape of microscopic crystals, or sand, appears in the kidney-tubules, colloidal cement is poured out, and the formation of calculus begins.

But this process is not a mere chance mixture, either as to quantity or as to form. Dr. William M. Ord, in his work "On the Influence of Colloids upon Crystalline Form and Cohesion," proves that it goes on under fixed laws; and he further says that "the pebbles of the concrete would not hold together without the cement to bind them, and act on their surfaces. To make calculi of uric acid without colloids would be as hopeless a task as making ropes of sea-sand."[1]

Calculus is most common at the two ends of life: young people and old people are most subject to it. There is a similarity in the pathological and anatomical conditions of both to favor its production.

It occurs much oftener in boys than in girls, and in men than in women. There is no reason whatever that the original elements of stone-formation should not be the same in both sexes, but females get rid of these by natural, short, and free drainage from the bladder.

On the other hand, boy infants often have abnormally long and adherent prepuces with very fine openings, and there also may be a urethra of small calibre especially at the meatus. Any physician who has noticed children thus afflicted must also have noticed their strainings when trying to pass water. I remember seeing one case where the pressure was so great and the opening so fine that a minute stream was projected twenty feet. The suffering is sometimes great, and there is this very natural action on the part of the baby. So soon as he feels relief he stops. He does not empty his bladder, and thus he has more or less residual urine always in it. And so, the other conditions being present, the formation of stone is favored, just as it is in the old man whose residual urine results from the mechanical obstruction of a large prostate and an atonic bladder. Once a man, twice a child, is illustrated in more ways than one.

---

[1] Ed. 1879, p. 61, London.

If this view is true, Jewish children, who are circumcised on the eighth day after birth, should not be nearly so liable to stone in the bladder as the children of the uncircumcised. I have made some inquiries on this point. The answers from different quarters have been only partly received. So far, they seem to sustain the view that the Jewish child is remarkably exempt from stone, but sufficient replies have not yet been obtained to warrant a conclusion in time for this article. When received, they will be made the subject of a special note.

It is not the purpose of this paper to enter into a description, both chemical and microscopical, of the different kinds of urinary calculi. This has been so thoroughly done by chemical experts, of whom the writer is not one, that it is not necessary to reproduce an account of their work here. We have given a brief abstract of the present knowledge of the origin of stone, have shown that it may be and often is congenital and hereditary, that sex influences it to a very great extent, the proportion of females to males who have it in the bladder being as five to one hundred, and the cause for this difference we have indicated to be anatomical rather than constitutional.

Occupation can scarcely enter into the consideration of stone in children. Social conditions and habits may have something to do with it. It is known that the poor, and especially the children of the poor, furnish by far the greater number of stone cases. Sir Henry Thompson says, "So common is stone in the children of the poor, comparatively speaking, that at Guy's Hospital, surrounded as it is by a very large neighborhood densely populated by some of the worst classes of the community, quite one-half of the cases admitted are children."

Mastin, speaking of age, and of the abundant supply of uric acid in infants, says that "this condition is doubtless the result of the rapid changes to which they are exposed only a few hours after birth, cold, light, and deficient or improper nourishment tending to disarrange the proper performance of the functions of their various organs. Taking into consideration their defective digestion, errors in their diet, the irritations of dentition, with the consequent excitement of the brain and nerve-centres, we find them in the pathological condition most favorable to the formation of a diathesis which, when acted upon by hereditary influences, will produce these deposits."

Poverty, then, with its surroundings favoring mal-assimilation, does its part in the production of stone, but gout is acknowledged to be allied to those conditions which produce calculi. Sir Henry Thompson says, speaking of stone, that "either gout or calculi will be traced in the family of nearly every patient who presents himself for treatment." Gout is said to be a disease of the rich and well-to-do. If this is so and the conditions are akin, it is curious that they should manifest themselves early in life in the form of calculous disease among the poor and later in life among the rich as gout. Are the healthful surroundings of the gouty man's child sufficient to eliminate his infantile tendencies to calculus? I am strongly of the opinion that, if the child has the elements of calculus deposited within him at birth, he will go on and become a victim of stone, in spite of his surroundings.

The poor vastly outnumber the rich. They are forced to public charities for relief, whilst the relative number of cases of almost any disease among the rich is a matter of conjecture.

The geographical distribution of stone and its race-affinities are most interesting studies. We must refer the reader to the various works and papers upon these themes. Thompson, Gross, Keyes, Mastin, and many others have written about them. We here repeat our opening remark more at large, and say, in passing, that wherever calculous disease exists, whether in China or India, in Europe or America, there infancy, childhood, and adolescence are bearing more than one-half of the sufferings and disabilities that it inflicts upon the human race.

THE ANATOMY.

The regional anatomy of the floor or outlet of the male adult pelvis is usually taken as the standard for beginning the study of those parts which are concerned in the various operations for stone in the bladder.

As the surgeon necessarily begins his work from without, this is as good a technical method as any other. It seems to the writer, however, that a much more philosophical and comprehensive understanding of the matter is to be had by studying the parts from within outward, not only with reference to their relations to other parts, but also as to their development.

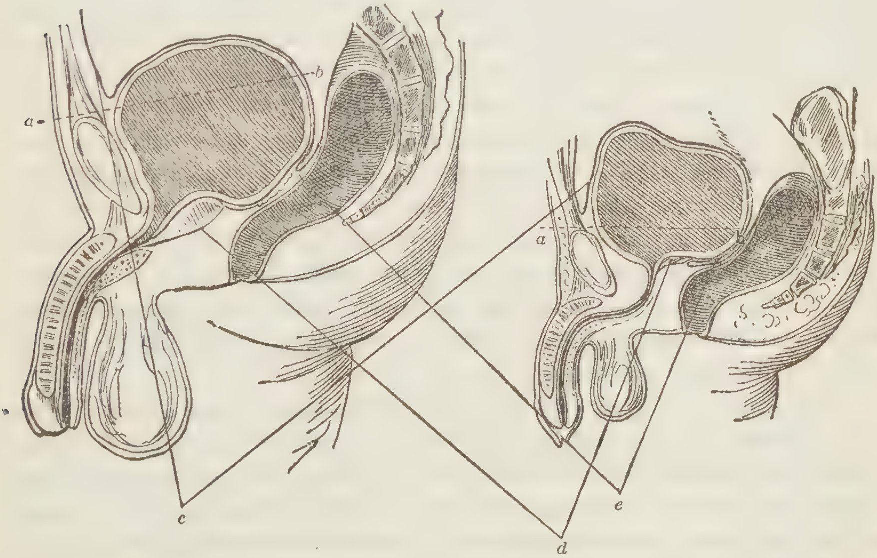
The reader is referred to the short but admirable description, by Dr. George McClellan, in the first volume of this work, on the Anatomy of Children.

The urinary bladder, developed from a portion of the allantois which remains in the abdomen in early fœtal life, is really an abdominal organ, absolutely at first, and more or less so during the whole period of childhood. The bladder therefore may be said to grow and to change its place from above downward until finally, at a time approaching puberty, it is fairly, though loosely, fixed, and hidden when empty, in the pelvis.

In the fœtus it may be said that there is no pelvis capable of holding it; in the infant the obliquity of the pelvis is so great as to form no part of its environment. The relative alterations of the pelvis to the rest of the trunk which sitting, standing, and walking effect bring it partially up to the bladder, which also may be said to descend and gradually to become attached behind the symphysis. The firmness of this attachment increases with age, and has an important bearing upon operative proceedings. (See Figs. 13, 22, and 30, pp. 20, 27, and 38, vol. i., for illustrations of these remarks.)

In contrast with these illustrations, the practical anatomist knows that the empty bladder is not seen on opening the abdomen of an adult in the ordinary way, either in performing a laparotomy on a living subject or in dissecting a dead one. It has to be looked for where its anterior and posterior walls are in contact behind the symphysis. I have frequently seen fresh students in the dissecting-room looking in vain for the bladder. The bladder in anatomical and surgical drawings is always represented as more or less distended, and this is correct, for its natural physiological conditions as to size are constantly varying. The same is true as to preparations, whether natural or artificial: so that it is incumbent upon the student of the surgical anatomy of this region to make due allowance for these constant changes of relation of the parts. The bladder itself may be so distended as to reach high in the abdomen, and it may be almost completely displaced by diseased or artificial distention of the rectum or by enlargements of the uterus of whatever kind. (See Fig. 3.)

FIG. 1. FIG. 2.



CONTRAST BETWEEN PELVIC CONTENTS OF AN ADULT MALE AND THOSE OF A MALE CHILD OF ABOUT SEVEN YEARS.—*c*, anterior folds of peritoneum; *d*, prostate; *e*, posterior folds of peritoneum.

Figs. 1 and 2 represent the contrast in position between the pelvic contents of the adult male and those of the male child of about seven years.

They were taken from a sketch, made by myself, of two beautifully preserved frozen sections, in St. Thomas's Hospital, London, which I saw through the kindness of Sir William MacCormac and Mr. Reid. The points of importance in relation to the operations for stone are seen distinctly. I know of no preparations concerning this operation that are more instructive. Above the pubis we have the anterior reflection of the peritoneum from the abdominal walls to the bladder, to which, at this point particularly, it is loosely bound by connective tissue. We can understand how upon distention of the bladder it may be readily pushed, or rolled up, as some say, to a considerable distance above the pubis, amply sufficient in the high operation without wounding it to gain access to the bladder for the removal of large calculi.

The peritoneum is more adherent to the bladder on the fundus, and also posteriorly, where it forms the vesico-rectal fold, which in the child is lower than in the adult and even partially covers the rudimentary prostate gland. We can understand how, in the lateral operation upon children from infancy to ten years of age, the whole of the small prostate is almost necessarily divided, notwithstanding the traditional cautions that are given against doing it. The relations of the rectum are well shown, and the possibility of wounding it in perineal operations may be readily appreciated.

Coming forward, we notice the ischio-rectal space (not shaded), a part more concerned in the accidents and failures of lithotomy than any other. The differences in the curves of the urethra owing to the positions of the bladder are seen. Notice by the lines *a b* (Figs. 1 and 2) that at least two-thirds of the young bladder when moderately distended are above the upper margin of the pubis, whereas two-thirds of the adult bladder are below the same level when distended to about a proportionate degree.

We now come to the bony margins of the outlet of the pelvis, which give attachments to fasciæ and muscles which, together with a varying proportion of fat and the skin with accompanying nerves and vessels, form the perineum or pelvic floor.

The anterior portion of the outlet, bounded by the ischiatic tuberosities behind and the lower margin or angle of the pubic symphysis in front, includes the perineum proper and the parts concerned in the perineal operations for stone. Sometimes the part between the anus and the sacrum is called the posterior perineum.

The deep fascia of the perineum, or the triangular ligament, much more pliable in the child than in the adult, fills the pubic arch below the symphysis and between the descending rami of the pubis as far back as the ischiatic tuberosities. It is here reflected forward around the lower borders of the transverse perineal muscles and becomes continuous with the deep layer of the superficial fascia.

The transverse muscles enveloped by these layers of fascia pass inward and forward from their attachment to the ischia to the perineal centre in front of the anus. The deep layer of superficial fascia is also attached to the anterior margins of the bony rami and symphysis in such a way as to cover the accelerator urinæ muscles in the middle of the space and the erectors of the penis at the sides.

The triangular ligament is perforated for the passage of the urethra, which here is called the membranous portion, and is so called until it is hidden in the bulb of the spongy body of the penis. It is this portion of the urethra in which the operator should feel the staff in the perineal operations for stone.

The anterior portion of the levator ani muscle passes downward and forward to the side of the prostate and is attached to the perineal centre. Mostly some of its fibres are divided in the performance of the lateral operation.

The superficial layer of the superficial fascia, mingled with varying proportions of fat, and the skin, bring us to the external surface of the perineum. While the muscles to the front of the perineal centre are covered with the fascias above described, the sphincter ani is subcutaneous. The junction of the deep and superficial fascias in front of the anus prevents urinary infiltrations, or abscess, from passing backward, and directs them forward and upward. The skin of the perineum is thin and pliable, especially so in children.

The arteries concerned in perineal lithotomy are the internal pudic artery, which is very rarely divided, and the bulbar artery, which is derived from it and which supplies the bulb and spongy portion of the urethra. This may be a source of troublesome hemorrhage. The transverse perineal artery, also coming from the pudic, is nearly always divided, and is easily controlled. The bulbar artery lies between the layers of the triangular ligament, as also do plexuses of veins, which may bleed so as to require special attention.

In the female, both adult and child, so far as operations for stone are concerned, the anatomy of the perineum does not come into consideration, as access to the bladder is had through the short urethra, or by the vagina, or by the high operation.

The anatomy of the high operation is the same in both sexes, and comprises a knowledge of the relations of the abdominal walls to the bladder in the hypogastric region, which will be detailed in the description of the operation. It is to be especially remembered that as to space the above account of the normal anatomy of the outlet of the pelvis is simply to be taken as a guide. Whilst in the adult measurements are fairly regular, in the child they are not only varying quantities according to age, but they also differ exceedingly in children of the same age. Thus, among forty measurements by Velpeau in young subjects, he found the tuber ischii in one case one and three-fourths inches apart, and in another four inches apart. There were many variations between these extremes. Some measurements which I made gave the same irregular results. It is not only the bones that vary, but all the growing tissues. For example, the muscles in an infant or a young child may scarcely be recognized. The lesson learned is that questions of space, both as to breadth and depth, must be determined by the skill and tact of the operator in the individual case.

This topographical account, the writer thinks, is all that is required here. For the descriptive or special anatomy of the parts the reader is referred to the works of Leidy, Gray, etc.

SYMPTOMS.

If the child has had from birth manifestations of the lithic-acid diathesis, as shown in stained diapers and obstinate colics, these will greatly aid in a true interpretation of what is apt to follow as he grows older.

Unfortunately, as most of the children with stone belong to the poorer and ignorant classes, it is rarely that one gets an intelligent early history. They are put through routine domestic treatment for colics, worms, bowel-complaints, and whatever else the wisdom of ignorance suggests. Even the medical attendant, where there is one, may not have his suspicions aroused for some time.

Facial expression is important. A child with stone is not a jolly, laughing child. Even in the intervals of suffering, however playful he may be, there are marks of distress in his face that do not belong to his fellows. He looks old. Mostly there is mal-assimilation and he is thinner than he should be; but sometimes, and especially early in the case, nutrition does not seem to be much interfered with. The local symptoms become more and more marked. There is growing frequent desire to pass water, and this is done with much straining and pain. The pain seems to be greatest as the last few drops of urine are passed out, and is thought to be due to the stone being compressed at the neck of the bladder. If there are mucus, pus, and blood in the urine at this early stage of life, they are almost pathognomonic. Pain is also felt at the end of the penis, and, whether from nervous transfer or from irritating urine, it makes the patient press the glans and pull at the prepuce. Unnatural handling of the privates, particularly in these parts, is a very constant symptom.

The reflexes from these irritations are also marked, and exhibit themselves locally, especially in the scrotum, but sometimes they may extend to all parts of the body. Dr. John H. Packard has recently had in the Pennsylvania Hospital a boy aged eight years who every fifteen minutes had general convulsions without loss of consciousness. He was brought in without any suspicion on the part of his relatives of the existence of a stone. Sounding revealed its presence, and upon its removal the reflex phenomena entirely disappeared.

A child with stone often takes peculiar positions to empty his bladder. He learns by experience the easiest way. Sometimes he will lie on his back, sometimes on one side or the other, sometimes he will support himself on the hands and feet. Again, he will raise his pelvis in some way, and cases are spoken of where the patient has nearly if not quite stood on his head.

The explanation of these positions is reasonable: they are supposed to cause the stone to fall away from the neck of the bladder.

Another common symptom is prolapsus of the rectum, with or without coincident evacuation of fæces. There is not often a case without this occurring with more or less frequency.

Urination almost always brings it on, and it may be so prominent as for a time to mask the real difficulty, the "putting up of the body," as it is called, being the frequent occupation of the mother or nurse, and often with the infliction of much pain. Whenever prolapse of the rectum occurs often in a child, stone in the bladder should be suspected as a possible cause, and the bladder should be searched.

Tenesmus is a common symptom, and there may be obstinate incontinence of urine.

What has been so far related pertains not only to very young children, but also to youth and in a great measure to the adult. The difference is that, as advance in years goes on and intelligence increases, the patient himself becomes more accurate in localizing and describing his sufferings. Although sometimes ignorance to a most remarkable degree exists as to the true cause of them, there is mostly some suspicion of the truth.

Moreover, every one of the above-related symptoms may be present and yet there may be no stone in the bladder. There may be stone, but it may be in the kidney or in the prepuce. Cystitis, not so common in the child as in the adult, may give rise to the symptoms detailed. Rectal troubles, prolapse from various irritations, as from ulceration and ascarides, may by reflex affect the functions of the bladder, apparently as seriously as though it were the principal organ involved. Disease of the kidneys and obstructions of various kinds are possibilities which may bring on excessive irritations resembling those of stone. Phimosis with adherent prepuce and irritating smegma may produce analogous symptoms.

DIAGNOSIS.

The diagnosis is to be made by the sound. It would be strange indeed to meet with a child having *all* of the above symptoms and find no stone upon sounding, yet this has happened. It is this possibility that makes sounding the crucial test of the presence of stone, and the conditions of this test are that the stone must be both *felt* and *heard*. The last condition is what gives name to the proceeding.

The projecting sacrum and the tuberosities of the ischia may be felt, but they will transfer no sound-vibrations through the instrument used, or at least no characteristic ones. The sensation is that of a dull thud and a fixity of the object impinged upon. A rugous bladder, or one with phosphatic deposit on its walls, is more likely to deceive, but the clear ring of most stones would also be wanting here.

Foreign bodies, which require the same process to ascertain their presence, differ as to the sound emitted by them according to their material.

Very young children may be excluded from consideration as to these objects, but boys and girls are known to have done strange things, or to have had strange things done to them, by the introduction of foreign bodies into the bladder. Glass tubes, pieces of wood, bodkins, crochet-needles, hair-pins, etc., have been passed into the urethra and have slipped into the bladder after escaping from the hands that held them. Pieces of broken catheter, not uncommon in adults, would scarcely be looked for in a young person. These different objects would, of course, influence sound. If long enough in the bladder, they form nuclei for stone, and then impart the sensations of stone. If a foreign body is the cause of the trouble, children suffering in this way are old enough to tell about it, but they mostly will not do so if they can help it. I know of a boy who bore untold pain for four years before he would tell that he had a piece of glass tube in his bladder. Sounding at once revealed its presence, and he was successfully cut as for stone. The writer has seen or had under care all of the above kinds of strange cases.

The process, then, is called sounding, and the name of the steel instrument is the sound.

Much judgment is required in selecting the proper size and shape of sounds, especially for children. By referring to the anatomical plates it will be seen that the child should be examined with one of shorter curve than that used for the adult. A great and dangerous fault of many sounds of the shops is that they are not blunt enough at the points. In fact, it is a good plan to have sounds narrower in the shaft than at the point, for if made in this way the shaft is not grasped by the walls of the urethra so tightly as to interfere with the delicacy of the movements, or of the sensations expected from the part which is in the bladder. Sir Henry Thompson's "searcher" is one of the best forms of sound.

Unless there are valid objections in the special case, sounding should always be done with the patient under anæsthesia.

The argument that if anything untoward should happen the child will express it by pain if he is not anæsthetized, has no weight in comparison with the real danger of damage that he may inflict on himself by his struggles. Violent spasm of his muscles and his cries may render the examination futile both as to feeling and as to hearing, and sudden and unlooked-for movements may cause great damage while the instrument is on its passage to the bladder, even although it be in the hands of the most experienced operator. Our fathers got on without ether, but they must have had a hard time.

The patient should lie on a bed or table, and pillows should be at hand to use in changing the position of the pelvis. A very young child may be held in the nurse's lap, but this is not advisable, as there are few nurses who could hold with the requisite steadiness. Sometimes a trustworthy and intelligent one may, by holding the child, move it into various positions if there is any difficulty in finding the stone.

The sound, being well oiled and warm, is held lightly but securely by the handle, and the surgeon should allow it to glide along the upper surface of the urethra, using little or no pushing force. Obstacles, so common in the adult, are not often present in the child, and, if one is mindful of the anatomy of the parts, there is rarely any difficulty in introducing the instrument.

Should a moderate-sized or large stone be present, it is mostly struck and heard at once, and its looseness in the bladder is recognized. It is not only heard and felt, but it is also felt to move, and may be made to rattle against the sound. So positive are these sensations to an experienced examiner, and, I may say, often to one of no special experience, that the nature of the case is determined, and it is unnecessary to do any more in this direction.

Size, influencing the choice of operation, may be estimated by tact, or by measurement, but the fact remains that the stone is there and that a surgical operation is necessary for its removal.

But the diagnosis is not always accomplished with this case. The stone may be very small and escape detection, until, the symptoms continuing, frequent examinations are requisite for absolute certainty of its presence. It may be struck at one time and not at another. It is extremely rare to find an encysted stone in a child or youth. One might be sacculated in a bladder of abnormal formation. In the young there is practically no prostate for it to rest behind in the base of the bladder. Again, the stone may be so covered with organic products as to prevent it from giving the usual sensation, and the sound may glide over it and even push it about without recognition by the examiner.

Under any or all of these circumstances, careful search is to be made in all directions with the point of the sound, and aid may be obtained by passing the finger into the rectum and pushing up the bladder, although this is not in children so often as good a help as it is in the adult.

Various positions may be tried, and a youngster may easily be held in them by a good nurse. The bladder may be injected with tepid water, in view of the fact that the stone may be held in its relaxed folds.

It is the history of stone, both in adult and in child, that one surgeon may detect it and another of equal experience miss it. The certain cases are so easy and the doubtful ones so hard: to say that a thing is, is a much lighter task than to say that it is not.

The practical bearing of these remarks is illustrated by the following quotation from Mr. T. Holmes. "It must be admitted, however, that the diagnosis of stone by the sound is not so easy but that experienced surgeons are often misled. I have seen the bladder opened in a child by one of the best and most experienced surgeons in London, where no stone was detected. Mr. Paget, of Leicester, has had the candor to publish a case of the kind in his own practice. I myself once opened the bladder, and the stone certainly escaped our view; but, as in that case I did not rely on my own judgment exclusively, and as those who assisted me heard as well as felt the stone immediately before the operation, I think I am justified in saying that there must have been a small stone which gushed out with the urine and was lost. In another case a child was put under my care by a surgeon of much experience in stone, and who had sounded the child as a case for immediate operation, in whom I could detect no stone; who died of another disease, and who was then proved to have no stone in the bladder."

The writer can confirm the above statements, for he knows of and has seen like cases in the hands of the best operators.

What has been said pertains to sounding when there is no question about the instrument being in the bladder. What must be the difficulties when one of the possible accidents occurs in the introduction of the sound!

The loosely-attached bladder of a child may be pushed before it. In this case the stone may be felt through the intervening tissues, but it will not be *heard*. It may be diagnosed as one covered with organic deposit. If the staff follows in the same course and the operation is proceeded with, it will be a failure unless the true state of affairs is recognized before the final steps are taken. There is nothing imaginary in this description. Experiences of the kind are on record.

Another accident is that of breaking through the delicate urethra of the child immediately anterior to its undeveloped prostate. There is naturally here but slight resistance to the push of an instrument in the wrong direction. Hence the injunction to press along the upper wall of the urethra if there is any necessity of pressing at all. No words can give an appreciation of the effects of this accident so well as a close examination of the cut on page 601. It will be seen that the sound at once enters the ischio-rectal space, where in the extremely loose and unresisting tissues of a child it may be moved about almost as freely as if it were in the bladder. There is nothing imaginary in this, either: it is something that has occurred and may readily occur.

These observations in reference to the sound apply to all other instruments that are used for entrance into the bladder through the urethra,—*e.g.*, ordinary catheters, injecting, washing, and evacuating catheters, staffs, lithotrites, and tubes or probes of any kind. We shall therefore not waste space in detailing them again when describing the various operations for the relief of stone.

OPERATIONS.

It having been determined that there is a stone in the bladder, a surgical operation of some kind is essential for its removal.

We may dismiss at once all thoughts of treating children by different waters and nostrums in the hope of dissolving the stone. To do this would be to prolong suffering without any gain, for the object would not be attained.

The operations are divided into cutting operations, and crushing or non-cutting ones. The cutting ones are the lithotomies, and are divided into the perineal or low and the supra-pubic or high operations.

The crushing ones are lithotrity, which consists in crushing the stone with an instrument called a lithotrite, the patient afterwards passing the fragments through the urethra along with his urine, and litholapaxy, which consists in not only crushing the stone but also immediately removing the fragments in a current of water set up by the use of a suction apparatus, the patient being under prolonged anæsthesia. It was an essential of original litholapaxy to finish the business at one sitting; but this rule is not so strongly in force as it used to be, for experience has taught that there is such a thing as keeping the patient too long under the operation.

Cutting Operations.—Two of the perineal operations are performed upon children,—the lateral and the median. To do any other than one of these is so exceptional as scarcely to require notice: so that our attention will be given to describing them. All that is possible in a bilateral operation upon children may be accomplished, if found necessary, during the progress of the median incisions.

The recto-vesical operation may be dismissed from consideration, for the writer can conceive of no case of very large stone in which the present methods of performing the high operation do not entitle it to the first choice.

Of lateral and median lithotomy the former has the preference of most surgeons in by far the greater number of cases. Up to the present time it would be difficult, without special cause, to induce them to depart from it, particularly in children. It may be fairly challenged whether there is any other capital operation in surgery that gives such a measure of success in young subjects.

It may be as well to state here, once for all, that all the operations are to be performed *antiseptically*. While, on account of the functions of the parts concerned, absolute antisepsis can scarcely be attained, it can be so in a great measure. The preparation of the skin, the use of solutions, or of hot water, at the choice of the operator, strict cleanliness, and non-interference of any one but those immediately concerned in the manipulations, are to be as carefully observed as in any other operation. The writer thinks, in reference to operations in general, that the time has arrived to regard this matter as axiomatic, and that its constant repetition in the reports of every proceeding in surgery is excessively tiresome and unnecessary. Antisepsis has come to stay, whatever alterations (and already there have been many) may be made in the details. At the same time he must protest against the tone of much of the teaching of the day, which seems at least to despise the idea of danger in any operation provided strict antisepsis is observed. We shall find, up to date, that lithotomy, like most other operations, still has its record of mortality.

Lateral Lithotomy.—When the lateral operation for stone goes on from beginning to end without mishap, the novice must be impressed with its extraordinary simplicity, and he must wonder at the necessity of dissecting so much, hearing so much, and reading so much about it.

He will soon learn that this is the only way, together with practice, by which the skill comes. In illustration, a case may be quoted which was in the hands of that great operator, Dr. Joseph Pancoast, at the Jefferson Medical College. I had a seat on the students' benches; the operator had taken up his knife,—when at that moment a student on the raised bench behind me rubbed his shoe on my shoulder. I turned for a few seconds to remonstrate, and when I looked again at the operator the stone was in his hand. I had seen nothing of the operation.

But the operation as to time and incident varies by wide extremes. Sometimes the patient may be an hour or more on the table before the stone is extracted, and sometimes there is no stone at all, or it cannot be found. I have been present on such occasions. They are well known in the history of lithotomy, and may happen to the skilled as well as to the unskilled.

For a straightforward, uneventful operation very few instruments are required. The sound having been already used, a staff, a knife, and a forceps are all that are absolutely necessary. The operator may get through without using anything else.

But this is not likely, so other things should be at hand: a syringe or a washing-bottle and a catheter if it should be deemed advisable to inject the bladder before or to wash it out after the operation; a scoop, small for a child, if it should be required to move fragments of stone and débris should the stone break; of course a tenaculum, hæmostatic forceps, and ligatures to control hemorrhage; various-shaped forceps if the simple one at first selected should not suit. The writer has extracted a stone from a small child with a polypus forceps or an ordinary dressing forceps. For special use there should be a probe-pointed knife and a blunt gorget, although I have never had occasion to use the latter or to see it used by others.

Care should be taken that the child's bowels are well moved on the morning of the operation. For lateral lithotomy the patient lies on his back, with his buttocks well brought down to the end of the table. This should be firm and not too high. An ordinary kitchen-table is as good as any other, probably better and firmer than many operating-tables with much movable rigging about them. It is well to have the perineum shaved beforehand if there is any hair, and always well cleaned. The child should also be etherized before being brought into the room, as the shock of fright is thus spared him.

It is unnecessary to use anklets or bandages to tie the hands and feet together. A good assistant on each side can easily keep the limbs in the proper position. They are to be held widely apart, with the legs in extreme flexion, the thigh flexed and away from the body and the leg upon the thigh. If the patient is large enough, the knee may be held in the axilla of the holder, whose hands at the same time grasp the ankle. The hands of the patient may require attention, but this is not likely if the anæsthesia is as profound as it should be.

The necessary assistants are the staff-holder, the two holders of the limbs, and the etherizer. These should absolutely have nothing else to attend to but their specific duties. A nurse, for general duties as required, should be present. The instruments are to be placed within easy reach of the operator. The bare perineum of the patient should be exposed to a good light.

If at the discretion of the surgeon any water or solution is to be thrown into the bladder, it is to be done now.

All the preliminaries as to diagnosis having been previously gone through, it is unnecessary to introduce the sounds again. But the staff itself must be used as a sound. The staff-holder or the surgeon may introduce it, but the latter should at once use it to satisfy himself and his colleagues that the stone is present. If he cannot do so, the rule is to stop proceedings for that time. The stone may have been small enough to have escaped from the bladder since the last examination, or the conclusions from that examination may not have been right. A small stone could readily pass through the dilated and yielding urethra of a child after a good sounding, and be lost or unnoticed by his nurse. If once engaged in the grasp of the urethra at the neck of the bladder, he has an immense pushing power to drive it through. Instances of this kind are on record.

The surgeon should examine the rectum, to be sure it is empty, and, having satisfied himself of the presence of the stone, he fixes the staff in the position in which he wishes it to be held, generally, in a child, hooked well up against the pubic arch; and he abandons it to the staff-holder, who stands mostly upon the left side of the patient, and who can thus more easily use his left hand to hold the scrotum out of the way, should this be required.

The surgeon, as he chooses, may stand, sit, or kneel on one knee. The sitting posture is usually preferred. The first incision is made through the left side of the perineum, beginning at the raphé, half-way between the scrotum and the anus. Exact measurements cannot be laid down as to the point of beginning or as to the length of the incision. In a very young child the latter may not be longer than from three-fourths of an inch to an inch; in a boy of eight or ten it may be from one and a half to two inches in length. We may judge of the variations when in a fully-developed adult an incision of four and a half inches may be obtained. The incision is oblique, and the low point given for its termination is half-way between the tuberosity of the ischium and the anus. However, many operators have no fear of free external incisions, rather thinking that they are more beneficial than not; and so the matter must be left to individual judgment.

The skin, the superficial layer of fascia, and the fat having been divided, the operator proceeds steadily on, but with more care. He deepens the middle part of the wound, cutting inward and rather upward; at the same time he follows the knife with his left index finger, for two purposes,—one to feel for the staff in the membranous portion of the urethra, and the other to press the rectum away from the knife. The parts divided at this stage are the transverse muscle, possibly some fibres of the levator ani, the deep layer of superficial fascia, connective tissue, and fat. The staff, covered by the membranous urethra, should now be felt without much search. It is well from the beginning for the operator to have his mind fixed upon a point just under the pubic arch against which the staff is held.

The distance of the staff from the surface varies according to age and the amount of fat, so that a young child may have a much deeper perineum than an older one. A depth of about a quarter of an inch from the surface is given by some authorities as the average in a boy of seven years. From the writer's experience he thinks that this is not enough.

But, be it shallow or deep, the staff must be found. When the operator feels it, he presses the pulp and nail of the left index finger against the groove for a guide and opens the urethra with the point of his knife. He knows that he has done so by the contact of the knife with the metal of the staff, and he should further test by moving the knife from side to side, so as to be sure that he is in the groove.

He now lateralizes his knife, the cutting edge directed downward and outward, and carries it along the groove of the staff into the bladder. In this movement he cuts through the membranous urethra, the triangular ligament, and the neck of the bladder, and doubtless in a child he has divided the whole of the small prostate and has incised the peritoneum. A slight flow of urine will indicate that the bladder has been entered.

The staff is still in place, and the wound is so small that there is not often a gush of water at this time. This is in children the most critical part of the operation, for now the surgeon, guided by the staff, must pass his left index finger into the bladder; and on no account should the staff be removed until this is done. The pliable tissues of a child may easily be pushed before the finger. But there is one unmistakable sensation, to be learned only by experience, when the finger enters the bladder. It is exactly like that of passing it through a button-hole. In a very young child the pulp of the finger only may pass. In larger children it will pass in by the side of the staff and often feel the stone.

The holder is now directed to withdraw the staff, and then comes a gush of urine, and the stone is generally felt, although, if small, it may have been forced out along with the water. But, being felt, the operator takes up the forceps with his right hand, and, guided by the finger of the left, he passes them into the bladder and seizes the stone, a movement which is sometimes aided by another gush of water, after withdrawing the finger, driving the stone between the blades of the forceps.

If the stone is small, it may be removed at once; if large, it must be extracted deliberately, for the possibility of the successful removal of large stones by the perineal route is founded upon the dilatability of the parts through which they and the instruments holding them must pass. To pull rashly at this stage may tear, and will stimulate contraction, but gradual traction and dilatation generally accomplish the object in a short time.

When the operator puts his finger into the bladder after extracting the stone, which he must always do in order to find out whether there are more stones, or whether the bladder is free from débris, he is always surprised at the small opening that has been made.

Any immediate hemorrhage must now be checked. The bladder should be washed out through the wound. The patient then is to be dried and prepared for bed. He should lie on a rather hard mattress, well protected by rubber cloth under the sheet. No particular dressing to the wound is required, but a thick layer of absorbent cotton should be placed beneath the buttocks, to receive the urine which at first flows altogether from the wound. This should be frequently changed by the nurse.

It is useless to try to force a child to lie in a fixed position. Let him seek his own comfort as much as he can. If he is too restless, bandage his legs lightly together from below the knees and up the thighs. There is, however, one imperative rule,—keep him in bed until the wound is healed. Great trouble may come from not doing this, especially incontinence of urine. Children do strange things sometimes without harm, but the risk from disobedience or carelessness in these cases is serious.

The time for recovery varies from two to six weeks. Children, especially those from the poorer classes, from which most of them come, should take nourishing but easily-digested food, as milk, eggs, etc., from the beginning.

This is the history of a smooth case of lateral lithotomy. Before considering the untoward events that may occur, we will give a short account of the median operation, as some of the unfortunate incidents are also common to it.

Median Lithotomy.—By the median operation access to the bladder is obtained through a central incision along the raphé of the perineum in front of the anus. A staff with a central groove is passed into the bladder and held in the same way as in lateral lithotomy.

There are now two ways of proceeding,—one which is often called brilliant, the other safer for most operators. In the first the index finger of the left hand is passed into the rectum as a guide against wounding it. The knife is then entered on the line of the raphé at a safe distance in front of the anus, with its cutting edge upward. It is pushed right on until it is felt in the groove of the staff. The surgeon must now be certain that he divides the urethra, of which he judges by the contact of the two metallic surfaces, just as in lateral lithotomy. He then withdraws the knife, and in doing so he enlarges the perineal incision from within outward and upward, according to the extent of the perineum before him, or according to the room which he thinks he may require. The staff is still held in place, and a long director or blunt probe is passed along its groove into the bladder. The staff is now withdrawn, and the surgeon follows the director with his finger. He feels the stone and removes it with the forceps.

The safer method, as we have called it, is to cut deliberately from without inward and from above downward until the staff is reached, the other steps of the operation being strictly observed.

The claims made in favor of the median operation are that it avoids wounding the prostate and the important blood-vessels of the perineum, and that it is simpler than lateral lithotomy. Against it, it is said that it gives less room, the structures are not so dilatable and are more apt to be torn, and there is a question as to its simplicity. It is therefore appropriate in children for the removal of small calculi and foreign bodies, for if these have entered by way of the urethra they may be also in most cases taken from it. Special considerations for its performance pertain to the adult.

In the operations described it will be noticed that the operator uses but one knife. This is a matter of choice, for many prefer after reaching the staff to change the first knife for a probe-pointed one. The old-fashioned cutting gorget is practically discarded. There is force in the objection to a probe-pointed knife, especially in children, that the parts may be easily pushed before it, so that they are not cut through at all, whereas the sharp knife cleanly and surely divides what is necessary. Of course the latter requires to be kept with greater care in the groove of the staff.

Complications.—Keyes, in his article in Ashhurst's "Encyclopædia," already quoted, enumerates seventeen possible complications during perineal lithotomy, fifteen after it, and four possible after-effects. These are surely enough to show that the path to recovery is not always smooth. Some of these are peculiar to the adult. Those which are common to both adult and child are the following.

Failure to Enter the Bladder.—This may occur from the staff, through some movement of the staff-holder, having slipped from its place, or from the incision being too small to admit the finger, or from the knife, particularly a blunt one, pushing the delicate membranous urethra before it, and possibly separating it from its connections. If the faulty conditions should not be detected and the operation is proceeded with, the operator will find himself working in the ischio-rectal space. If detected, the first fault is to be remedied by replacing the staff. If the incision is too small and the operator does not get with his finger the unmistakable sensation of having entered the bladder, he should not, in the child at least, persist in his efforts to do so, and thus risk pushing the bladder before him, but he may carefully enlarge the incision, or, what probably is better, he may introduce a director through the wound and by the side of the staff into the bladder. The staff may then be withdrawn, and there should be no difficulty in passing the finger along the director, as in median lithotomy.

Wounding the Rectum.—It is said by some that this is a common event in children, and that in them the wound mostly heals along with the legitimate incisions. There may be some cases where the accident is unavoidable, but the writer thinks that with care it should not occur. A small wound requires no treatment at first. If obstinate, its edges may require cauterizing before it will close. Larger wounds may be stitched, but to have to do this is rare.

Hemorrhage.—We will speak of this both as a complication of the operation and also as secondary. There is not often in children much trouble on this score. The bleeding points are more readily got at than in an adult. The ordinary instruments before mentioned, together with hot water or hot alum-water, will mostly be all-sufficient. If not, the shirted canula or the small rubber air-bag may be used. The writer never saw a case in a child where they were required. There is sometimes troublesome after-bleeding. The bladder fills, and it is hard to tell where the blood comes from. It may be from the kidneys. If from the deep parts of the wound, the pressure of clot may be advantageous. Washing out should be done with hot alum-water, and in these cases, if the source of bleeding is made out to be from venous plexuses about the wound, plugging may be resorted to.

Dr. Brinton recently had a case in a boy who had several such hemorrhages, exactly from where was not found out, but, notwithstanding, the patient made a good recovery.

The child sometimes dies of exhaustion without any loss of blood, and in spite of all efforts, by appropriate nourishment and other treatment, to counteract it.

Failure to Find the Stone.—We have seen this happen in children from causes already mentioned. A small stone may come with the first gush of water and be unperceived. Of course it cannot be found in the ischio-rectal space should the searcher be working there. In children we can hardly claim that the stone is encysted, but it may be held by muscular contraction or by a band of lymph. The writer was witness of a case in a child in whose bladder after a long search the stone was found attached above the pubis in some mysterious way. The child recovered.

Sometimes there is no stone at all, and never has been one. How this may occur, even with men of experience, has already been explained in the section on sounding.

Retention of urine from swelling or clot happens in children. When from swelling immediately after the operation, the child soon learns to pass water by the urethra. As the swelling subsides, the urine again flows through the wound. This is an important thing for ignorant attendants to be instructed about, for they naturally think that the child is much worse when the flow through the wound comes the second time. When retention is owing to clot, it may easily be removed, or a female catheter may be made to penetrate it. Suppression of urine rarely, if ever, occurs in children. If it does, it is due to some general cause and is to be treated accordingly.

Peritonitis is agreed to be the most frequent cause of death among the few fatal cases of operation for stone in children. The proximity of the peritoneum to the wound and its almost necessary involvement in the lateral operation may explain this. But the mortality of the median operation is equally great. In these days of vast experience as to the safety of peritoneal wounds under proper precautions, the explanation is not satisfactory. It would be interesting to know whether in the fatal cases of peritonitis following lithotomy in children the patients have not been subjected to undue handling, from causes or mishaps heretofore mentioned. A clean cut into the peritoneum, which is almost necessarily made in the lateral operation in children, could not fairly be charged with the fatal result without something more to induce it.

Peritonitis is to be treated as in other cases of the malady. Salines should be given, and opium, if used at all, very sparingly. Advantage may be taken of the wound to keep up free drainage and washings and to make local applications.

Among the *after-effects* of lithotomy in young subjects there may be incontinence of urine. This generally ceases in time. Probably it comes more from too early getting about after the operation than from any other cause, and is therefore a matter of prevention rather than of cure. When it is obstinate, cauterization of the neck of the bladder has in some cases proved effective.

Sterility is said to be one of the permanent consequences of the perineal operations, and a few post-mortem examinations showing obliteration of the seminal ducts and vas deferens would seem to sustain the view.

Anatomical considerations should make division of the ducts exceedingly rare, and, besides, in the operation most often done (the lateral) but one side is involved. In the cases quoted by writers there is no proof of what the condition was before the operation. Surely nothing could be imagined more likely to bring about obstructive lymph-deposits and inflammatory thickenings than the long-continued irritations of stone in the bladder.

In this connection the writer has a curious experience to relate, which shows how that which is quoted as positive authority may have very little or no foundation.

Of late the enthusiastic advocates of supra-pubic cystotomy have dwelt much on sterility following the perineal operations. Thus, Dennis[1] quotes Halberstadt, of Pottsville: "Halberstadt reports eighteen lateral lithotomies in which the patients, having grown up, married, and only one out of these eighteen cases had issue;" and Dr. Tremaine[2] is reported thus: "He then reviewed the dangers which accompany the cutting operations for stone which reach the bladder through the perineum. One of the most important, and one which is too often entirely disregarded, he said, was that of impotence. As evidence of this he referred to eighteen cases of stone, all in young boys, which had been operated upon by a surgeon in Pottsville,

---

[1] Transactions of the American Surgical Association, 1887, vol. v.

[2] American Medical Association, Newport Meeting, 1889: Medical News, Philadelphia, July 13, 1889, p. 50.

Pennsylvania. The subjects of the operation have all since grown up, have married, and but one of them has become a father. While there were many other ways of explaining sterility, he thought that under the circumstances so large a number of successive cases argued strongly for its being due to the operation." The observation about the eighteen has become famous and is quoted repeatedly.

Dr. T. S. K. Morton was at the Newport meeting and heard the debate, and in telling me of it afterwards (never doubting the statements) he said there was a tone of mutual satisfaction prevailing at having such definite and strong support in favor of the high operation.

But I wrote to Dr. Halberstadt. He answers, July 7, 1889, "Two of my subjects, cut between the ages of seven and ten, grew up, married, their wives had children, *in one case twins.* I have every reason to believe the children were legitimate, as the paternal resemblance was marked."

The eighteen turned up somewhere else in my reading, and I wrote again. This is from the answer of September 29, 1889: "I *did not* follow eighteen who married, but lost sight of them after recovery from operation; I do not know how many of the eighteen married." He then refers to the two cases above mentioned. Dr. Halberstadt is now anxious to find the origin of the statement, for he says, October 30, 1889, "It cannot be possible that any such information ever came from me." While he does not deny that perineal operations may be a cause of sterility, he has had no such experience about the eighteen with which he is credited.

Stone in Female Children.—This is rare, the proportion being about one case in the female to twenty cases in the male. Anatomical reasons forbid any operations like the perineal ones done on the boy. Besides pain, prolapse of the rectum and incontinence of urine are the prominent local symptoms. The child also handles the parts, but not to the same extent as the boy does. A straight or slightly-curved sound should be used for diagnosis.

The patient must be etherized, and it is a good plan to have instruments ready to crush or to remove the stone should it be small, for nothing like the formidable preparations for operation are necessary that are required in the boy.

While there are no true perineal operations, the stone is often removed through a perineal route,—that is, by way of the female urethra. Girls are more apt to have foreign bodies, as hair-pins, etc., in the bladder than boys, and the operator should be mindful of this.

The dilatability of the female urethra even in young children is really astonishing. It is this fact that allows them to get rid of small stones without artificial assistance, and, on the other hand, it is the same fact that may make the surgeon presume too much, so that his operation is apt to be followed by obstinate and sometimes incurable incontinence of urine.

The surgeon really begins his perineal operation in the female at the corresponding point which he is anxiously striving to reach with his staff and knife in the male. If there is any structural resemblance between the male and female urethras at these points, there is no difficulty in believing in Dr. Otis's utmost dilating possibility.

Moderate dilatation alone serves for the removal of small stones, and the forceps may be used both as a dilator and as a remover. But sometimes greater dilatation is required, and this may be done by either the rapid or the slow process.

The slow method consists in introducing a screw-forceps and opening it by increasing widths every day, and also catgut bougies may be worn in the urethra in the interim, or they may be exclusively used. That this gradual and careful dilatation does not tear is doubtless the case, but, when the final work comes of getting out the stone, it is questionable whether any advantage as to after-incontinence is gained over the rapid method, and so the latter is most in vogue.

In rapid dilatation the screw-dilator is used more quickly, or bougies of increasing size are inserted one after the other. The finger as soon as it can be introduced is best of all, for it not only dilates, but the bladder at the same time is examined, the stone felt, and a conclusion arrived at as to whether further pursuit of this method of removal is to be continued. The dilatation having been accomplished, the stone is seized by a forceps and extracted.

Cutting operations in order to dilate more easily and to gain more room consist in incising the urethra in various directions. The names of high authorities, and their peculiar methods, are given in works on surgery.

Some cut upward, some downward, and some laterally; some only a fraction of an inch, and some an inch.

The writer thinks that, while in some cases a small incision might do no harm, still in these days of litholapaxy there is no necessity of making them, as great harm might follow. Permanent incontinence in the female is much more to be dreaded than impotence in the male. When discussing lithotrity and litholapaxy, operations on female children will again be noticed.

The High Operation. Supra-Pubic Cystotomy.—The method of extracting calculi through an incision above the pubis is ancient, and has a history most remarkable as to origin, progress, decadence, and revival.

As an illustration of its once complete disappearance from surgical favor, Carpue quotes an "eminent practitioner" as saying, when he was discussing some point in practice, "Gentlemen, it is as absurd to talk of this as of the high operation for stone." Of late the operation has been revived, and, as a contrast to the above condemnation of it, we will quote one of the enthusiasts in its favor in this decade: "Within ten years the supra-pubic operation will be the operation adopted for all cases of stone that are not treated by Bigelow's operation."

We can merely allude to the historical phase of the subject here. Much has been written, in many languages, about it. The writings of Carpue,

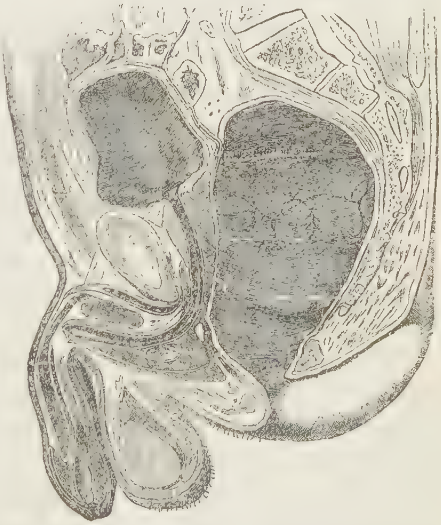
C. W. Dulles, Sir Henry Thompson, Packard, Dennis, and many others are of great value and interest.

This article is concerned in the applicability of the operation to cases of stone in children. A large number of the supra-pubic lithotomies that have been performed both in former and in recent times have been upon young persons. What is peculiar in the anatomy of the bladder and its relations to the pelvis and peritoneum has already been described (page 602). A knowledge of the anatomy of the abdominal walls common to so many operations is the other topographical requisite.

The high operation has undergone many modifications. As late as 1880 the *sonde à dard* was considered an essential instrument, or it was substituted by a solid catheter or an ordinary sound. These instruments are passed through the urethra; the blunt ones are pressed against the bladder-wall from the inside, and, being felt by the surgeon through the abdominal incision, they become his guides for entering the bladder. The *sonde à dard*, an old contrivance, contains a sharp steel grooved stylet which is made to pierce the bladder-wall and appears in the external wound, thus making a most excellent guide.

Now these operations are mostly discarded, and the method in vogue is based upon the power of a distended rectum to push the bladder upward and forward against the abdominal walls. See Fig. 3 in illustration of this. It is reduced from the figure in Sir Henry Thompson's small volume on the supra-pubic operation. It is taken from one of the frozen sections of Garson. One would be apt to think it is an exaggeration; but I saw in the summer of 1889 one of these preparations in Edinburgh, and I can confirm the truthfulness of the cut in every particular.

FIG. 3.



The operation is simple. First a colpeurynter or india-rubber bag is greased and introduced into the rectum, and through a tube with a stopcock attached it is injected with water or, preferably, a boracic-acid solution. If there is no stopcock, the rubber tubing or mouth of the bag may be tied. Then, through a flexible catheter introduced into the bladder, this viscus is injected with the same solution and the base of the penis is tied with a piece of rubber tubing.

Both injections should be made slowly, and a nice point is to judge correctly as to quantity. An average for an adult is from twelve to fourteen ounces for the rectum, and from eight to ten ounces for the bladder. It is to be remembered that a young bladder is naturally higher than that of the adult and much more lightly attached below. The quantities of fluid required for children, therefore, are not nearly so great, but must be determined according to age. From less than one-half to two-thirds of the amount for adults may be used; and the surgeon's tact must come in, for when he feels the bladder rise and present a good projection in front it is time to stop. Nearly all the serious mishaps in this operation have occurred from ill-judged injections in both rectum and bladder; for the patient, be it remembered, is under anæsthesia and can through his sensations be no guide.

The operator stands on the right of the patient. He makes a longitudinal incision immediately above the pubes and in the median line. The skin, superficial fascia, and fat are divided, and the linea alba is brought into view; this may be slit up on a director, and the muscular fibres separated by the handle of the knife or by the fingers. Sir Henry Thompson uses an ivory separator, which is preferable if at hand.

The transversalis fascia is now reached, for there is no posterior tendinous layer of the sheath of the rectus in this position. This fascia may also be divided with the separator. In children it is very delicate. Beneath it some yellow fat will be found; under this is the bladder, which, if injected rightly, should be felt without difficulty. In this approach it is of great advantage not to use the knife, as abundant veins are in the connective tissue about the symphysis.

After recognizing the vesical wall and clearing it for a small space, a tenaculum is introduced into the bladder. If it has entered, a few drops of water will flow out. Retaining the tenaculum in place with the left hand, the operator with his right makes an incision through the bladder-walls large enough to admit his index finger. He now judges of the size of the stone, and, if necessary, he enlarges the incision. He should not cut too freely downward towards the neck of the bladder, as not only troublesome hemorrhage but also dangerous infiltration might ensue. He may cut upward more freely, keeping the peritoneum in mind. But in either case dilatation with the fingers is preferable, and the knife should only be used as a necessity.

The bladder at this stage must be kept well up to the abdominal wall, for the water flowing out will cause it to fall away if not supported. It is good practice in some cases to introduce a loop on each side of the incision and let an assistant support the parts by them. Size permitting, the best and safest forceps for withdrawing the stone is made by the two index fingers of the operator. He locks his other fingers together, and introduces the indexes into the bladder, one on each side of the stone. He then by pressure seizes the stone and withdraws it. This plan failing, forceps of different patterns may be used. Scoops also are sometimes required.

The bladder is now examined for other stones or débris, from which it is freed. If necessary, the patient may be placed on his side, and the bladder washed out through a piece of tubing.

The essential operation is now completed, for the question of suturing the bladder is still an open one. If done at all, it must be done thoroughly, and even after this the sutures are apt to give way.

In many cases it is a process of great difficulty, and the necessary or injudicious extra handling may do great harm, not only in itself, but also by prolonging the operation. Besides, experience has taught that the cases do equally well, if not better, without it. The old operators never did it. Sir Henry Thompson did not do it in eight cases which he reports. One of these only, an old man, died. Dennis condemns the practice in stone operations, but thinks it best to follow it for other causes, as in rupture. He quotes twenty-five stone cases, collected by Schmitz, in which suturing was done. Six of these died, and in only four did primary union occur.

The practice, then, of not suturing being followed, the patient lies at first on his back and then shifts from side to side. The water may be drawn by the urethra through a soft catheter three or four times daily, and what does not come this way drains from a tube in the wound for the first few days and then without it. The tendency to contract and close is great, and shortly all the water passes by the natural outlet. Young children, of course, cannot be made to understand the importance of co-operation as to position in the after-treatment, but much may be done to aid them by a judicious nurse.

The dangers of the high operation are said to be—1st, from opening the peritoneum; 2d, from extravasation of urine. Careful operating should render the first almost impossible, and, even if it were to happen, with the present methods of treatment the danger is not great.

The second incident is no more dangerous than extravasations after the perineal operations, and may be as readily combated. It mostly comes from faults in the operation, such as too much working low down and so disturbing the vesico-pubic space.

I. Greig Smith, M.A., F.R.S.E., in his work on Abdominal Surgery, 1889, says, in the article on supra-pubic cystotomy, "Taking the case of young children first, we often hear it said that for removal of stone in the bladder we do not want a better operation than lateral lithotomy. Recent work in crushing would seem to show that here we have already got an operation at least as good as, probably better than, lateral lithotomy, while as regards remote results there can be no comparison." He then mentions some of the almost incurable evils, as perineal fistula, traumatic stricture, etc., that he knows to have followed perineal operations. He mentions sterility, and quotes Halberstadt's immortal eighteen, and then continues, "Stricture, fistula, sexual incompetence,—separately or combined,—must be admitted to be rare sequences of perineal lithotomy. But that they are possible sequences cannot be denied. Now, if the supra-pubic operation can show immediate results as good as the perineal, and a complete absence of remote drawbacks, then the supra-pubic operation should be selected. Even if the percentage against the perineal were as small as one, this one case for fixing a rule in sound surgery should be decisive. In children, therefore, I should say that, where the crushing operation is negatived, the supra-pubic should be adopted. A further argument in favor of its adoption in children is the favorable position of the bladder and the usual healthy condition of the involved tissues."

In reply to the above the writer would ask, Suppose against the supra-pubic operation the mortality percentage was two, which operation should be selected? It would seem that there is an assumption of nothing against the supra-pubic operation, which does not agree with the record.

Whatever may be said as to deliberately choosing the high operation for stone in preference to all other cutting operations, most surgeons, I think, are now agreed that it is *the* operation for stones which are much above the average size.

Sir Henry Thompson as late as 1886 gives, as reasons in support of this view, that there are no important structures to be wounded in the incisions, greater space for removal is obtained, there is no danger from hemorrhage, the operation is easy, the urine leaves the bladder more directly than by the lateral method, and antiseptic dressings may be effectually employed. The dangers from over-injection of both rectum and bladder have already been spoken of. This over-injection, by producing rupture, is a serious and mostly fatal event, and should be particularly guarded against.

In female children, as the bladder is already high, it alone may require injection. Where the generative organs are not developed to any extent, a rectal bag might be used with advantage. As before stated, this method of removing a large stone in females is preferable to the risk of having permanent incontinence of urine by incising the urethra.

NON-CUTTING OPERATIONS.—**Lithotrity.**—Old-fashioned lithotrity is no operation for children. A small soft stone, particularly in a girl, might be crushed with a lithotrite or forceps and be allowed to come away with the urine or be washed out, but experience is against any general application of the method to patients under the age of puberty. In fact, it may be said now to be almost abandoned even in cases of adults, and to be but an essential part of the operation to which we shall now give attention, that of

Litholapaxy, in which lithotrity, or the crushing, is the first step, and litholapaxy, or the immediate evacuation of the fragments under prolonged anæsthesia, is the second and final one.

The general fitness of the operation for children is still a matter of doubt, but the verdict of many trials is decidedly in its favor in well-selected cases. There are those who reject it, and those who advocate it, with almost the same intensity of opinion as in the examples given in the section on the high operation.

The names of Bigelow of Boston, Otis of New York, and Sir Henry Thompson are inseparably associated with this method of removing calculi from the urinary bladder. It was Otis's demonstrations of the dilatability of the male urethra without injury to its structure or functions that made litholapaxy possible, for by them it was proved that evacuating catheters of large calibre could be safely passed into the bladder.

The historical details of the rise of litholapaxy will not be treated of here. Keyes, in Ashhurst's "Encyclopædia," and others have written of them in full. As in most other matters of the kind, there is a history of slow growth and unsatisfactory efforts to accomplish a desirable end, until at last the one entitled to be called inventor appears, and in this case that honor is due to Bigelow.

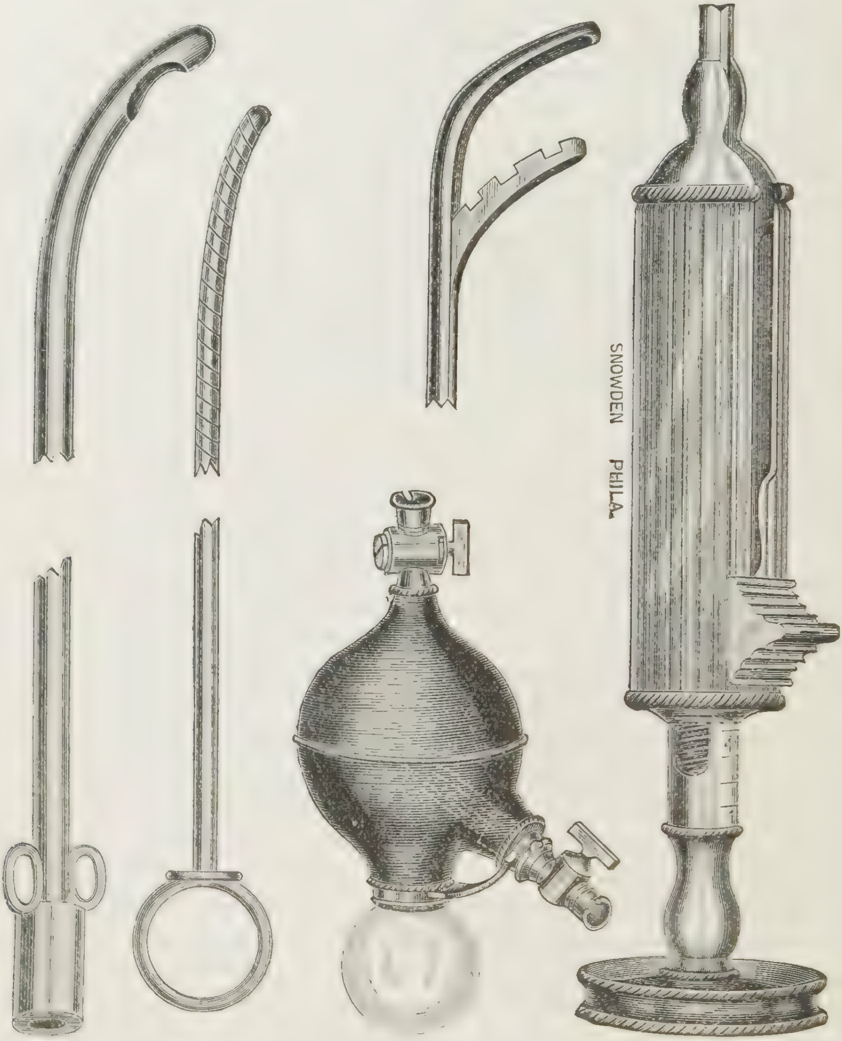
Sir Henry Thompson accepted the operation and has done much to perfect its methods; and Otis, as we shall see, has worked in the same line and produced an original apparatus, besides having the glory of discovering the most essential fact on which the operation is founded.

We will in this article confine ourselves to an account of the use of the Bigelow and the Otis apparatus, as either of them may be readily used in cases of children. The same bulb or washing-bottle may be used in any case, but particular attention must be given to the size of the evacuating catheter and the lithotrite, according to the age.

Bigelow's latest evacuator (Fig. 4) consists of an elastic rubber bulb, to the lower end of which is attached a glass receiver. Opposite this at the upper end a metal stopcock is inserted. By this the bottle is filled. To one side of and above the glass receiver there is another metal stopcock fixed in the bulb, and to the short tube projecting from this stopcock the evacuating catheter fits when the instrument is in use. There also projects from this opening into the bulb a finely-fenestrated tube open at the end. This last is to prevent fragments of stone returning to the bladder, and to catch mucus, coagula, etc., for it will be noticed that the obliquity of the fixtures here directs the current away from the receiver, so that fragments of stone by gravity fall directly into it after leaving the tube. There are no valves, and no tubing. The piece of tubing in many pictures is not essential, but is only a convenience for filling the bulb by suction, for which also a funnel is used, but the bulb may be easily filled by immersing the whole of it after opening the stopcocks. An essential point, especially for children, is the workmanship of the eye of the catheter. There should be nothing cutting or projecting about its edges, but these should be blunt and turned a little inward. A stylet accompanies it, to be used if it gets choked. Great harm could come to the delicate structures of a child from any defect in the instruments which are to be introduced into the bladder.

Much is said about the preparation of the patient for the operation of litholapaxy. This may be advisable in some adult cases, but the writer would suggest whether in children at least it is not time lost to spend days in giving medicines, washing out the bladder, etc. Cases of all kinds in surgery, and particularly chronic ones, among which stone cases rank, improve so rapidly when the cause of their trouble is removed and so stubbornly resist any treatment when it is not removed, that one is forced to believe that the sooner positive action is taken the better it is for all concerned. The great incentive to recuperation is the removal of the irritating cause. If the child is not sick in any other way, and if his bowels are clear, he is ready for the operation.

FIG. 4.



The assistants required are the etherizer, one to attend to the bottle and to refill it during the different crushings, another for general purposes, and the nurse.

The patient is to be laid on a narrow table which has been covered with a blanket, a rubber cloth, and a sheet; his hips should be elevated with a pillow. The evacuating catheter should be first passed, to empty the bladder of urine, so that a clear comprehension may be had of the amount of fluid which is to be thrown into it.

In the mean time the bottle or bulb has been nearly filled, say, with a borax or boracic-acid solution (than which there is no better). To clear the catheter from air, withdraw it into the urethra, then with the bulb compressed attach it to the catheter and remove the pressure. The air will pass through the water and remain at the top of the bulb.

The catheter is passed back into the bladder and two or three ounces of the solution are thrown in, and the whole apparatus is withdrawn, for now all is ready for the lithotrite.

This the operator uses to his satisfaction by crushing the stone as thoroughly as he can. In most cases suitable for the operation in a child, one introduction of the lithotrite and a thorough use of it should be sufficient. To go through this step of the operation more than twice at one sitting is scarcely advisable, but, as in adults, the condition of the patient must be the guide.

The crushing being done to the satisfaction of the operator, the lithotrite is withdrawn. The evacuating catheter is introduced, and some of the crushed stone will flow out through it. It is then fixed to the bulb, which is filled with the solution, after withdrawing any air as before, and the bulb is worked by alternate pressure and relaxation of the hand of the operator. Thus a current is set up into the bladder by pressure and out of it into the bulb by relaxation. This latter current brings with it the fragments of stone, which fall into the receiver entirely out of the way of the current, so that they are not stirred up again, sometimes to return to the bladder, as was the case in some of the former contrivances.

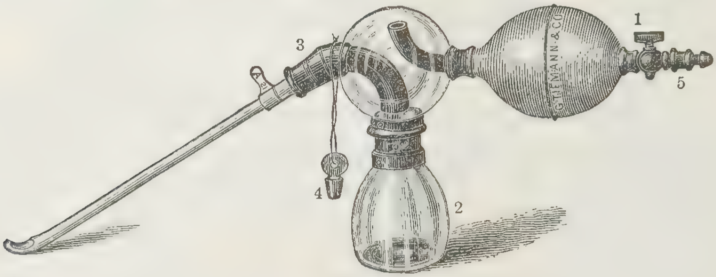
A considerable amount of blood and mucus often comes with the fragments, but unless excessive this should not give alarm. At times the view of the fragments in the receiver is obscured. Glycerin in the bottom of it is recommended to prevent this. When all the fragments that can be obtained have come away, the catheter is withdrawn, and the crushing and washing are repeated, at the judgment of the operator.

From the above it will be seen that at no time, if properly managed, is there much, if any, increase in the quantity of fluid in the bladder, so that danger from extra pressure is not great. The bladder, the catheter, the bulb, and the receiver are really parts of a continuous chamber, and it is the current set up in it that does the cleansing work. After carefully searching and listening for final fragments and finding none, the operation is completed, and the patient must be put to bed.

Otis Evacuator.—We will now give a description of the Otis perfected evacuator in the inventor's own words:

"The Otis 'perfected evacuator' consists of a strong glass globe, two inches in diameter (the reservoir), into one side of which a hard-rubber tube (3) is inserted, curving down to its lowest part. The superior end of this tube connects directly with the proximal end of the evacuating catheter. To the floor of the reservoir a strong glass bottle (the receiver) is connected by screw-threads moulded on the necks of the receiver and the reservoir respectively, and fitting a hard-rubber collar, into which the corresponding screw-thread is cut. On the side of the reservoir opposite the tube connecting with the evacuating catheter is another tube, of smaller calibre, curving upward to near the top of the globe. By this means the current

FIG. 5.



The Otis perfected evacuator.

is so directed that it flows between the two tubes, leaving the receiver below a perfectly dead point; fragments dropping into it by their own weight remain quietly there without the intervention of traps, strainers, or valves, and, this part of the instrument being entirely transparent, it is easy to observe that the fragments do not return to the bladder. Connecting with this tube of entrance to the reservoir is a strong rubber bulb, which in some form constitutes the power in all the modern evacuators. A small stopcock has been inserted in the end of this bulb, for convenience in introducing fluid into the bladder during operation. This is the only stopcock connected with the instrument, as the atmospheric pressure is found to be sufficient to retain the water in all positions necessary during operation. In case, however, it becomes desirable to lay the instrument down on its side, a hard-rubber plug (4) has been added which fits the tube of exit. The joints of the instrument have all been constructed in such a manner that they are brought tightly against the glass by means of screw-threads, so that freedom from leakage is assured, there is no cementing substance to give out, and the surgeon himself can take the instrument entirely to pieces, either for cleansing or to replace an injured part. To fill the instrument it is only necessary to submerge the end of the tube of exit and by repeated pressures of the bulb the air will be replaced by fluid. Should any air still remain, it is of no particular import, but may be entirely removed by submerging and inverting the instrument, when the air can then be let out under water.

"After a crushing, the lithotrite having been removed, a suitable tube is introduced into the bladder, and whatever fluid remains is allowed to flow out, carrying with it a certain amount of débris. The evacuator, which has been filled with fluid (preferably a saturated solution of boric acid), is then attached to the catheter, an ordinary Davidson's syringe connected with the stopcock at the end of the bulb, and any desired quantity of fluid easily and exactly introduced into the bladder. Pressure of the bulb with a quick relaxation will be followed by a shower of débris into the receiver, and this is to be repeated as long as any fragments appear falling into the receiver, when another crushing should be made. Should any bleeding be present, it will, by rendering the fluid opaque, make it difficult to tell whether fragments are falling or not: this may be avoided by filling the receiver with glycerin, which, owing to its specific gravity, will remain clear and unmixed, the fragments falling readily through it. This experiment also offers conclusive proof that the receiver is entirely out of the current.

"This instrument, on account of its lightness and small size, is particularly adapted for operations on children. It is not at all necessary to use a smaller instrument for them, as is the case with lithotrites and tubes, but with evacuators it is the current set up which removes the débris, so that, contrary to a very common supposition, a large volume of water is not forced into the bladder, but only one or at most two ounces. It must be remembered that no force is necessary, and especially with the delicate bladders of children should the greatest gentleness be used.

"In regard to the size of instruments to be used in the urethræ of children, this may be determined with sufficient exactness in all cases by measurement of the flaccid penis. The proportionate relation between the circumference of the urethra and that of the penis I have already demonstrated.[1] According to this, the average adult penis, measuring three and a quarter inches in circumference, is found to indicate a urethral calibre of thirty-two millimetres' circumference, this increasing or diminishing by about two millimetres of circumference for every quarter-inch added to or subtracted from the circumference of the penis as above cited. This proportionate relation holds good equally in children. Thus, with a circumference of penis of one and a half inches, as in a child from two to three years of age, the size of the urethra would not be less than sixteen millimetres' circumference, one and three-fourths inches eighteen millimetres, two inches twenty millimetres, and so on. I have never known this estimate to prove excessive; on the contrary, it usually falls short of the true normal calibre by one or two millimetres. It must be borne in mind, however, that this has no reference to the size of the urethral orifice, which is subject to very great variations, having no fixed relation to the calibre of the urethra behind it. If not of normal size,—*i.e*, of the calibre behind it,—and not readily dilated up to that size, the orifice should be carefully divided, always inferiorly, to the required dimensions. There is a considerable advantage in attending to this not unimportant detail, and allowing the parts to heal, before the operation of litholapaxy is performed."

In connection with the above, the fact should not be overlooked that localized contractions are sometimes met with in the urethræ of children. They are probably never congenital, but the result of an antecedent lithiasis. The failure to pass an instrument of the size indicated by the proportionate relation existing between the size of the penis and that of the urethra calls for an examination with the bulbous sound, which will readily indicate the extent and locality of the contractions. Such strictures, as in the case of contracted meatus, should be divided previous to the operation of litholapaxy.

---

[1] See Otis on Stricture of the Urethra, preface to second edition, p. vi., also p. 242; Diseases of the Male Urethra, pp. 6 and 40 *et seq.;* Genito-Urinary Diseases and Syphilis, Students' Edition, p. 441 *et seq.*, Putnam's Sons, New York.

Very few litholapaxies on young children have been done in this country. Dr. P. Allen reports four successful cases, but the subjects were all in their teens.

Abroad, however, great success has attended the operation, as will be seen in the statistics below. A child three and a half years old will take a No. 8 English catheter with safety. Owing to the dilatability of the young female urethra, well-conducted litholapaxy is admirably adapted to cases in that sex.

STATISTICS.—A goodly portion of this volume might be occupied with statistical tables of operations for calculi, with their results, both in the old times and in the new. What interests us here are the results of the operations upon children. From early times all the cutting operations have been practised upon them, that of lateral lithotomy much oftener than any of the others.

Deductions from figures have only a general application, as so many circumstances enter into the individual case that we are not justified in determining on a certain operation merely because the tables give the best record for that operation. We shall therefore give only the latest figures from operations upon children, advising any one more deeply interested to consult the innumerable tables in various surgical works.

The following letter[1] very well represents the success generally obtained in the perineal operations:

"**Statistics of Perineal Lateral and Median Lithotomy.**—A few months ago my friend Mr. Reginald Harrison wrote to me with a request that I should supply Prof. S. W. Gross, of Philadelphia, with a tabulated statement of all the cases of lateral and median lithotomy performed on infants and boys up to fifteen years of age in the Wolverhampton and Staffordshire General Hospital. Mr. Gough, house surgeon, at some trouble, grouped together all these particular cases of operation from the hospital books, and the list was forwarded to Prof. Gross; but, his lamented death soon afterwards having doubtless prevented its publication, I feel that, as the record is one of practical interest and value, I ought no longer to refrain from making it known.[2]

---

[1] T. Vincent Jackson, F.R.C.S. Eng., London Lancet, August 24, 1889, p. 367.

[2] When the plan for this work was under consideration, Prof. Samuel W. Gross, of Philadelphia, engaged to write the article on "Stone." He manifested great interest in the

From 1864 to 1888 inclusive, of lateral lithotomy—there were performed—

On cases from	1 to 5 years	inclusive,	70	operations,	with	2	deaths.
" " "	6 to 10 years	"	47	"	"	2	"
" " "	11 to 15 years	"	13	"	"	1	"
Median operations were performed—							
On one case of	15 years,		1	"	"	0	"
" " "	11 years,		1	"	"	0	"
			132	"	"	5	"

Two of the five, two and three years old, died of shock, one, nine years old, of peritonitis, and one, fourteen years old, of secondary hemorrhage.

Between	1 and 5 years	there was one death in	35	cases.
"	6 " 10 "	" " "	23½	"
"	11 " 15 "	" " "	13	"

the mortality being between three and four per cent."

After relating the method of making up the table and showing how wholly trustworthy it is, Mr. Jackson concludes his remarks thus: "I do not think it desirable to lengthen this short paper by copying the lithotomy tables and the conclusions which are to be drawn from them which are to be found in various published papers, monographs, text-books, and surgical treatises, as I wish these observations to be considered a contribution to the very important subject of perineal lithotomy in male children and boys, especially as at present the employment of other operative methods of dealing with this particular surgical disease is being strongly recommended to be adopted, as it were, to the effacement of that time-honored operation for the removal of stone from the male bladder,—viz., the great English surgeon's improvement of Frère Jacques' method."

The High Operation.—Sir William MacCormac, F.R.C.S., gives the following statistics.[1] In fifty-five recent foreign cases in children the mortality was twenty-three and three-fifths per cent.; in thirty-three recent British cases in children there were no deaths; and in twenty-five cases in children from the table in Vander Veer's paper in the "Transactions of the American Surgical Association" for 1887 (vol. v.) the mortality was eight per cent.: *i.e.*, in one hundred and thirteen cases in children under fifteen years of age the mortality was ten and one-half per cent.

When we consider that for this operation the cases are as yet selected, mostly because they are unfitted for other methods, the record is remarkable, that of the British cases particularly so.

Litholapaxy.—Keyes, in an article in the "Annual of the Universal Medical Sciences," vol. iii., 1889, gives the following figures. In Surgeon-Major P. J. Freyer's operations in the Bengal medical service sixteen

---

subject, and proposed to write an article which should give the results of his own experience and include statistics derived from his large correspondence. After his death Mrs. Gross placed at my disposal the matter he had collected; but it was found impossible to make any use of it. Dr. William Hunt thereupon kindly acceded to the request to prepare the article.—EDITOR.

[1] British Medical Journal, March 19, 1887.

litholapaxies on children were performed, without a death. The youngest child was three and a half years old.

Dr. P. Allen's four cases, all successful, aged respectively thirteen, thirteen and a half, fifteen, and nineteen, have already been noticed. Dr. Keyes says these are apparently the first of the kind in this country.

H. H. Clutton operated successfully on a male infant of three years in St. Thomas's Hospital, London. He used a No. 5 English lithotrite and a No. 9 English canula.

E. Hurry Fenwick, of London, records a successful case in a male child aged nine. He collected and tabulated the results in one hundred and six cases of the operation on children, thus:

Between	1	and	2	years,	6	cases,	no deaths.
"	2¼	and	3	"	10	"	"
"	3¼	and	4	"	13	"	1 death.
At			5	"	16	"	no deaths.
Between	6	and	9	"	34	"	"
"	10	and	15	"	27	"	"
					106	"	Mortality, 0.9 per cent.

Surgeon-Major D. F. Keegan, of Indore, records, with table, one hundred and fourteen litholapaxies in young boys, done at the Indian Hospital by himself, Surgeon-Major Caldecott, and Mr. Gunputsingh. There were four deaths.

The showing is remarkable, even more so than that of the high operation, and certainly is encouraging enough for the advocates of the more general adoption of litholapaxy in children.

In addition to the above are to be cited the latest returns of Surgeon-Major P. J. Freyer.[1] Since the sixteen cases were operated upon, sixty-four male children have come under his care. Litholapaxy was performed in thirty-three of these with complete success. It was tried in all the cases, but in twenty-nine he found it necessary to resort to lithotomy. The difficulty, he says, is in procuring the proper-sized lithotrites. The smallest he possessed up to September, 1888, was a No. 7. He then received a No. 5 from Weiss, and since then he has performed Bigelow's operation in twelve out of thirteen cases. He says he has now performed forty-nine litholapaxies in male children and three in female children, without a death. He naturally thinks that litholapaxy will practically replace lithotomy in children. The average weight of the stones in the children was one hundred and twelve grains.

The skill and enterprise of the surgeons of the East, together with their abundant opportunities, give their experience great value. If instruments of the proper size and strength for children are the important requisite, they will soon be forthcoming.

---

[1] British Medical Journal, October 12, 1889.

It has often seemed curious to the writer that the recent improvements in stone operations should have originated in places where stone itself is by no means a common disease. Comparatively few cases are operated upon in the northeastern cities of the United States, and most of these come from a distance. Lithotomy upon a New Englander used to be spoken of as quite an event in surgery.

CONCLUSIONS AS TO OPERATIONS.—From the foregoing the writer is of the opinion:

1st. That *lateral lithotomy and median perineal lithotomy* still hold and are likely to hold the first place in the minds of most surgeons of this day for the relief of male children from stone in the bladder.

2d. That the *high operation* is advisable in boys in selected cases of very large stones, or for some other particular reason in the especial case. In girls where even a moderately large stone is too hard for the lithotrite, this operation should be performed.

3d. *Litholapaxy*, admirably adapted for girls, is still on trial for boys. There is not yet enough evidence in its favor to justify one in saying that it will largely replace perineal lithotomy and so take the first place in the list, but, from what has just been quoted of Freyer's experience, it looks very like it indeed.

PREVENTION OF STONE IN CHILDREN.

As we have seen, most of the patients are from the poorer classes, and are the subjects of ignorance and unfavorable surroundings. If the cases were recognized in the early formative stage, much might be done by the use of proper diet and diluents to work a cure. It seems to the writer that in this stage the deleterious material might actually be washed from the kidneys. The mother's milk, the most fitting, and a properly-diluted cow's-milk diet, are often wanting. Instead of these, all sorts of artificial and often inappropriate substitutes are given. Not only among the ignorant, but even among those who ought to know better, the last thing that occurs to them is to give a child a drink of water. Expensive mineral waters are not required, for the most noted waters in the treatment of stone seem to have purity as their chief recommendation. Plenty of milk and plenty of water, therefore, should be given to an infant having any tendency to stone. Circumcision will help in cases where the condition of the prepuce interferes with free outlet. Beyond attention to clothing and to other general hygienic requirements, the writer has nothing further to suggest.

PROSTATIC, URETHRAL, AND PREPUTIAL CALCULI.

Prostatic stone is very uncommon in children. A case is related by Ebel which occurred in a boy of three years. As the prostate gland at that age is rudimentary, it was probably a case of local infarction at that point, just as infarctions occur in the kidneys, and the stone, which was not removed until after six years, kept its place and grew, as development of the gland was going on. Median perineal lithotomy would be the right operation to perform for the extraction of a stone in this position, should ordinary means to dislodge it into the bladder fail. If dislodged, the case would be a proper one for litholapaxy or lithotomy. A very extraordinary case as to size and attachments might require the high operation.

Urethral calculi proper sometimes form in the dilated follicles, the fossa navicularis, etc. More often they are due to the escape of small stones from the bladder, and not infrequently fragments after lithotrity lodge in the passage. Sometimes several stones are found in pouches formed by pressure and dilatation or even existing naturally; but such cases as these are scarcely to be looked for in children.

If after diagnosis, which is made by the sound or a blunt probe, the stone or fragment is not easily moved towards the meatus by gentle manipulation, or is not readily seized by the forceps or a wire loop, it is the best practice to push it back into the bladder and then crush it. If it is very fast in the urethra, this will have to be incised, but, if possible to avoid it, do not incise between the fossa navicularis and the scrotum, as most obstinate fistula may result. Wounds behind the scrotum near the membranous portion heal kindly.

True *preputial calculi* in children or in adults are not common in this country. They are said to be so in China. Small stones may pass from the bladder through the meatus and be held, owing to the preputial opening being too small.

What we often see in children is calcified smegma which collects about the corona and even becomes buried beneath the membrane in cases of phimosis. These cases give rise to symptoms precisely like those of stone. But it does not answer always to rely upon the operation of circumcision for a complete cure, although circumcision is the thing to do. Always sound the bladder after the operation, for just the state of things exists that is spoken of on page 598 to favor the formation of stone in the bladder. I had this experience. A lad was circumcised, as all his symptoms were attributed to his very bad phimosis and hard smegma. He was not sounded before leaving the table. He was only partially relieved. He was brought to me, and on sounding I found there was a large stone in the bladder. I cut him, and he recovered perfectly.

For the preputial conditions mentioned, circumcision and the thorough removal of the offending objects constitute the radical treatment.

MALFORMATIONS OF THE PENIS, URETHRA, AND BLADDER.

By De FOREST WILLARD, M.D.

GENERAL OBSERVATIONS.

Few cases of deformity more earnestly demand the thorough and conscientious consideration of the surgeon than do those affecting the genito-urinary organs. Even disfigurements of the face, though more apparent to the public, are not more potent in their effect upon the possessor.

The reason is obvious. The mental influences controlling and governing the genital function are of the most subtle and peculiar character, and are consequently more prone to aberration. A degree of deformity which would be simply an annoyance if situated on some other portion of the body becomes when associated with the genitalia so mind-absorbing that the individual is rendered morbidly sensitive and at times becomes almost a sexual monomaniac.

Relief, therefore, from what may be but a blemish becomes at times imperative for its psychical effect.[1] This psychical element will have much to do with the question of

Time for Operation.—Unless there is some interference with the necessary functions of life, or some resultant retardation of development, it is not advisable to adopt operative measures of relief until the child has passed the dangers of the first three years of life. By six, however, his companions will begin to annoy him by unkind remarks, and by the age of puberty he may become morbidly unhappy. From three to six, moreover, the child's healing powers are active, and the necessary time required for certain operations is unimportant. This age, therefore, is the one to be selected, as a rule.

At the marriageable age many who have hitherto shrunk from exposure will apply to the surgeon for relief, and in many instances I have found that it has been by the injudicious advice of their physician that they have waited "until they were older."

---

[1] I have seen a man voluntarily debar himself from marriage and almost from society on account of a simple hydrocele; and there are many instances where lives have been rendered lonely and miserable by an exaggerated estimate of disability or defect.

Marriage.—When the obstacle to marriage is insurmountable, as in the absence of the uterus or the penis or other essential organ, the physician should give careful instruction to the parents, in order that an early guard be maintained. I have seen most distressing results where it has been imperative to check an alliance after all arrangements had been completed.[1] This question will be still further considered under the head of spurious hermaphrodism.

Degradation.—Another morbid direction in which the aberration of a genitally-deformed individual may tend will be that of degradation, provided the malformation be disgusting to himself and to his neighbors, as in exstrophy or extreme hypospadia. Feeling that he is shunned and reviled, the downward steps become easy, or the mind receives a sexual bent and self-pollution or unnatural relations become the habit of life.

This cause alone is sufficient to deter a wise physician from delaying beyond five years of age any form of operation that promises a reasonable hope of improvement. Too often the sad results have been produced by an ignorant or procrastinating physician who has been lacking in the patience or in the skill that is so often required.

The laity are excusable to a certain degree in their neglect of conditions that are not pain-producing, but it is incumbent on the profession to educate the people not only in this class of cases but also in all other deformities of the body, since success in life is dependent in a large degree upon the removal of every hinderance to physical and mental development.

Every orthopædic surgeon is compelled to spend months in the correction of bony deformities in large children and in adults, which at birth were but slight malformations. Frequently these exaggerated conditions are due to the "let-alone" policy of the physician, who should have known that the early weeks of life, while the parts were soft and pliable, were of the most vital importance for corrective purposes.

In genital deformations there is sometimes an excuse for waiting one or two years, but there can be none for delay beyond five, if progressive surgery offers any hope whatsoever for improvement of the condition.

When the absolutely essential organs of child-bearing are absent, or the malformation is so great as to preclude the possibility of the production of children, it is good surgery to unsex the patient, be it either a male or a female, before it reaches the age of ten.

Laparotomists remove the ovaries for far less potential reasons, and, judging both from animals and from the history of the eunuchs of the past, the individual thus produced would be a more useful member of society, and would also be saved the degradation that so often is associated with the malformation. If this operation is done at an early age, great benefit will be obtained in this direction, and under the circumstances the loss of sexual desire will prove a blessing, as the psychical result of the defect will be less depressing, and may prevent actual insanity.

---

[1] Only a few years since, I saw a young lady upon the very verge of marriage, in whom there was no trace of a uterus, and the vagina was but a slight cul-de-sac. Unfortunately, she had been placed in this unhappy position by an ignorant physician, who, unaware of the absence of the uterus, had professed to form a vagina for her, but had really laid open her urethra to the base of the bladder, leaving her with the urine constantly dribbling into a rudimentary vagina.

Occasionally reports are seen in both medical and popular journals citing the connection between ill-developed genital organs and congenitally deficient or removed tonsils. While such coincidences are not infrequent, yet, when we take into account the far larger number of persons whose tonsils have been excised and yet the individuals have remained abundantly fertile, we can hardly consider that the relation has been established.

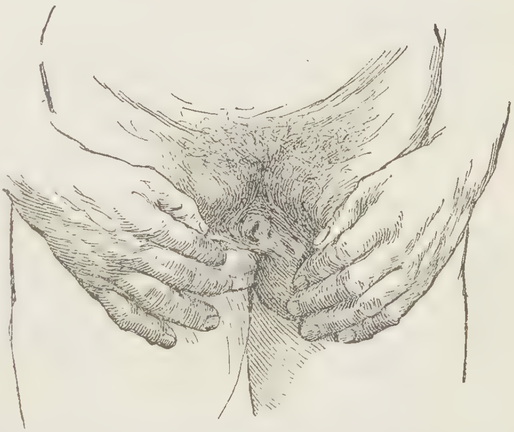
In Zanzibar all boys have their tonsils excised before puberty, but atrophy of the testicles is quite unknown, and procreative power is certainly not deficient.[1]

ABSENT OR DIMINUTIVE PENIS.

The penis is rarely entirely missing, except when other serious deformities are present. Some years since, I saw a still-born child in which there were neither genitalia, arms, nor legs; and similar cases are occasionally reported,[2] the infants ordinarily dying in a few days.

An apparently absent penis is often found to be only a greatly diminished organ, as in spurious hermaphrodites (Fig. 1), or it is concealed beneath the integumentary folds of a cleft scrotum, or the scrotum is present and the penis buried in the fat of the mons, where it can be distinguished as a small firm cylinder. A few years since, I saw a penis thus buried that required two or three operations before it was properly liberated and fashioned.

FIG. 1.



Sometimes urine is found issuing from an orifice at the lower portion of the abdomen, in which case diligent search will disclose a concealed penis.

Occasionally the penis is absent and the scrotum present.[3] In such cases the defect may have been occasioned by an imperfect fusion of the septum between the anterior or uro-genital portion and the posterior or anal portion, thus producing a broken or bridged condition of this cloacal wall. Such an imperfect closure would not only give rise to absence of the penis from non-appearance of the genital eminence, but might also misguide the urethra so that its orifice would be in the rectum or in some fold of skin.

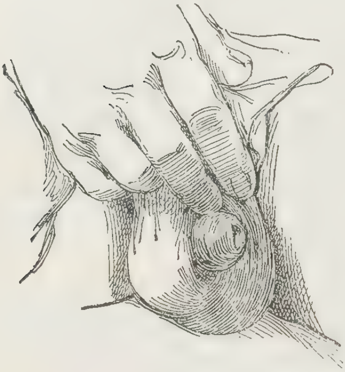
[3] Brit. Med. Jour., February 23, 1889, 409.

FIG. 2.



In one case both penis and anus were absent, the fæces returning by the mouth for forty years.[1]

Sometimes the body of the penis is excessively short and only the glans appears. (Fig. 2.) In very fat children where a diminutive penis is hidden by a firm and contracted prepuce, the surgeon will often be consulted in regard to this condition.

The early release of the glans, as described under Phimosis, p. 641, will usually result in the development of the organ. When the penis is buried in the scrotum or mons, it should be liberated by an incision, and an integumentary covering provided by flaps taken from the most available neighboring skin.

ABSENCE OF THE SCROTUM.

The scrotum is frequently altered in shape from cleavage and other causes, but it is seldom entirely absent except when multiple deformities exist. I have seen one case in a still-born child where neither scrotum, penis, vulva, nor anus existed; and a case is reported in which the left half of the scrotum containing one testicle was present, but there was no pouch upon the right side, the right testicle being concealed in the canal, without any coexistent hernia.

The concealment of the testicle in a fold of skin and its non-descent (monorchidism or cryptorchidism) are, of course, frequent conditions, and will be elsewhere discussed. In hypospadic conditions the scrotum is sometimes scarcely distinguishable. (See Fig. 14.)

WEBBED PENIS.

In hypospadic or other deformities of the genital organs the penis is sometimes bound down by a band of integument to the scrotum below[2] or is attached to the pubes above, in which condition it is said to be *webbed*. The organ in such cases is usually diminutive, and unless care is used in diagnosis an error in sex may be made.[1] Sometimes the penis and testicles seem to be enclosed in a common pouch.[2]

---

[1] Agnew's Surgery, ii. 613.

[2] Brit. Med. Jour., September 6, 1879, p. 727, Pick.

Treatment.—The restraining band should be divided by an incision upon each side, so as to yield sufficient flap for an integumentary covering for the penis. The movable skin of the region will permit easy closure of the gap in the scrotum. The operation should be performed thoroughly aseptically.

CONGENITAL OCCLUSION OR STRICTURE OF THE URETHRA, OR IMPERFORATE URETHRA.

The meatus of the urethra is not unfrequently closed by a simple membrane,—atresia urethræ. Partial or complete obstruction of the canal by a congenital or an acquired band of tissue may also occur at any portion of its extent.[3] Again, the closure may be occasioned by collapse of the tube from a hypospadic opening posteriorly, as in Ashhurst's case.[4] Sometimes the walls seem agglutinated through the entire length[5] at birth, or the corpus spongiosum is absent,[6] even when the penis is of considerable size.

If the stricture is within a few lines of the meatus, the stream of urine is greatly scattered and broken.[7]

Treatment.—If the obstruction is at the meatus, a simple incision, with subsequent dilatation, will suffice. Deeper in the tube, forced but careful catheterization or internal urethrotomy will best succeed.

In a case of considerable absence of the female urethra, pressure may be made beneath the pubes by a dumb-bell-shaped instrument,[8] in order to retain the urine.

CONGENITAL CYSTS OF THE PENIS.

This vice of development is rare. The pouch may connect with the urethra, as in Anger's case,[9] or it may be separate.[10] In the former case it should be excised, and the opening closed by quilled sutures. In the latter case incision and packing, to promote healing by granulation, would be advisable.

Congenital cyst of the prepuce is also occasionally met with in infants. Excision with scissors or knife is usually easy.

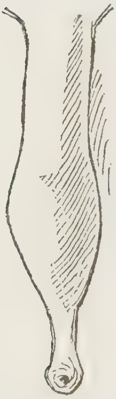
ADHERENT PREPUCE, AND ELONGATED, CONTRACTED PREPUCE, OR PHIMOSIS.

Adhesion of the prepuce and contraction of the prepuce are two distinct conditions, although they frequently coexist.

Adhesion is almost constantly present at birth, as a continuation of the normal intra-uterine agglutination, occasioned simply by a failure of the cells of the rete Malpighii sufficiently to condense or harden. During the first weeks of life this union is so slight that it can be separated with the greatest ease. In time it may become quite firm, as a result of slight inflammation.

A *contracted prepuce, phimosis* (*φιμόω*, "I bind"), rarely exists at birth, but is the result of an inflammatory condensation of preputial tissues. Elongation is ordinarily a later result. (Fig. 3.) When an attempt is made to retract an adherent foreskin the orifice will seem to be at first almost pin-hole in size, but after a moment's manipulation slight rigidity of the penis will occur, and soon the reddened meatus will appear.

Fig. 3.



In a circle just behind this or at some point in the circumference of the glans will be found the line of adhesion. In contracted cases it may be impossible to expose the glans, but exposure is feasible in a far larger proportion of cases than is ordinarily apparent at first sight. I have shown in other writings how easily this is secured by patient manipulation.[1]

Atresia præputii tends by pressure upon the glans to dwarf its growth, and adhesion necessitates the accumulation of smegma, which may harden and act as a foreign body.

Reflex Nervous Disturbances from Genital Irritation.—To Sayre[2] is due the credit of prominently bringing before the profession the reflex nervous disturbances due to the irritation of retained smegma and to the presence of a contracted foreskin upon the balanitic structure. Pursuing the subject with his usual vigor, circumcision became the cure for every nervous condition with rash and unthinking practitioners, until he himself was compelled to "call a halt."[3]

Even to summarize what has been written upon this subject would fill a volume,[4] but it is now very generally conceded (1) that genital irritation is frequently the cause of various reflex nervous, choreic, or paretic conditions, and (2) that the removal of this condition by the various means hereafter mentioned is frequently curative, and is almost always beneficial.

---

[1] Archives of Pediatrics, 1886, iii. 385; Phila. Med. and Surg. Reporter, July 25 and August 1, 1885; Phila. Med. Times, June 30, 1883; Trans. Ninth Internat. Med. Congress, Washington, 1887, vol. iii. p. 473.

[2] Trans. Amer. Med. Assoc., 1870.

[3] Trans. Ninth Internat. Med. Congress, Washington, 1887, vol. iii. p. 462.

[4] Phila. Med. Times, June 30, 1883; New York Med. Times, September, 1884.

Neuroses dependent upon reflected irritation from stomach, eye, nose, uterus, etc., are frequent. The genital nerves are confessedly the most sensitive of any in the body, and both the anatomical[1] and the physiological explanations of reflected results are simple.

The most common of these results are incoördinate and choreic movements of the limbs, paresis, feeble muscular action, malnutrition, convulsions, epilepsy, dysuria, nocturnal incontinence, prolapse of the rectum, and hernia. Symptoms resembling those of stone in the bladder are not uncommon, and hip-disease,[2] spinal caries, and bow-legs have been attributed to this cause. In the latter cases the result can be thus referable only through the influence upon general nutrition.[3]

In young infants many cases of restlessness at night, of defective nutrition, and of malassimilation have been greatly benefited by attention to the genital organs, and the puny, irritable, wakeful boy has been rendered plump and happy by simply giving him a clean, exposable glans penis.

Even when the amount of retained smegma is not large the uncleanliness of the parts will often set up severe vesical irritation, and is also conducive to priapism and masturbation.

Occasionally the loss of muscular power does not involve all the muscles of the lower extremities, but only one group, thus simulating club-foot or other deformity.[4]

Another reflex symptom recently noted is epistaxis,[5] probably due to the relation existing between the genital organs and the varicose venous plexuses of the nasal mucous membrane, which closely resemble erectile tissue, as demonstrated by Ischwell, Elsberg, and others. In lower animals this association may be even more intimate. Reflex cough and convulsions are common.[6]

No physician is justified in overlooking this causal element of disease, and in every obscure case a careful investigation of the state of the genital organs should be instituted: in fact, it would be the part of wisdom to ascertain in every male child the fact that the prepuce and the glans are separable. If family practitioners would gently separate the delicate adhesions in all young male babies, a vast amount of good would result.

Acquired phimosis is found in large boys, from balanitis or other inflammatory troubles, especially gonorrhœal.

Diagnosis and Prognosis.—A diagnosis of the actual condition is usually easily made, but upon its degree will depend the question of treatment. The method of testing the exposure of the glans has been already described.

---

[1] Trans. Ninth Internat. Med. Congress, Washington, 1887, vol. iii. p. 471.

[2] Barwell, Diseases of Joints, 2d ed., 1881, 289.

[3] New York Medical Abstract, July, 1888; Rev. Méd. de la Suisse Romande, 1888.

[4] Agnew's Surgery, 1st ed., vol. ii. p. 427.

[5] Archives of Pediatrics, November, 1888; Rev. Mens. des Mal. de l'Enf., June, 1888.

[6] Lancet, April 27, 1889, p. 835.

The diagnosis of the relation of the genital irritation to the reflex symptoms when they are present will, however, require careful study. In general terms, if the contraction is great, the adhesion firm, the accumulations of smegma large and hard, and the orifice of the urethra very sensitive, it is quite probable that these conditions bear a causal relation to the reflex symptoms.

Even when these conditions are present, however, it must be remembered that they may be but one factor in the case, and that other causes must be earnestly sought. Too frequently a serious brain or spinal lesion has been overlooked simply because the boy had an adherent prepuce, the practitioner apparently forgetting that nearly all boys have this condition.

To promise an immediate gain in muscular power when feeble action is due to deficient central nerve-cells is but to lose the confidence of the patient and bring discredit upon the operation. While such feeble or idiotic children should be given the benefit of the doubt, that genital irritation might be an element in the production of their condition, yet the prognosis should be guarded and central causes should be thoroughly investigated and treated.

While, therefore, a freely-moving prepuce or an uncovered glans should be secured *in every case where reflex symptoms arise*, yet the prognosis should be varied according to the other existing conditions.

In girls with irritation or hyperæsthesia of clitoris or nymphæ, incoördinate movements are sometimes seen, but the prognosis of recovery after separation of adhesions is not so favorable.

Selection of Operation.—In deciding upon the method of relief in any case, the surgeon must clearly differentiate the two classes of cases,—*i.e.*, those of *adhesion* and those of *contraction*. He must also settle clearly in his own mind the desirability of a covered or of an uncovered glans. To attain to the normal standard is to secure a *prepuce moving freely over a healthy glans*. The foreskin is intended to protect the head of the organ during the years when the penis is but a portion of the urinary apparatus, and later by its friction over the sensitive corona to enhance the ejaculatory orgasm.

If removed earlier than intended, a progressive sclerosis or hardening of the glans occurs, and the evils of contracted meatus, balanitis, etc., follow, as pointed out by Otis, Mastin, and others.[1]

I have failed to find any statistics proving that the circumcised masturbate less frequently or are more virtuous than others, and the exposure of the tender skin to friction of clothing, etc., tends to keep up a state of abnormal excitement during the early years of life.

The sulcus after circumcision is no more cleanly than the one that is daily washed, and such washings should be always insisted upon in the case of children. When carefully done by the mother, and not by the nurse, it occasions no excitement, and is the best of preventives against masturbation and priapism. It is as important to be continued through life as is the washing of face or hands, and after a few days' practice no more excitement is aroused even in adults than by the handling of the organ in urination. If commenced in youth it is looked upon as an ordinary act of cleanliness and will prove most hygienic. Even if it were the duty of the surgeon, as some operators allege, to prepare boys for future vile intercourse, such an individual is no more free from danger of contagion than the one who has thoroughly cleansed his exposable glans, since cicatricial tissue is always the tissue that is the least resistant to infection. It is for this reason that the prepuce should be retained whenever it can be made freely movable, since when cleanly it is of great advantage to the individual.

---

[1] Archives of Pediatrics, 1886, iii. 388.

Its removal is a mutilation. It is idle to argue that because imposed in the Mosaic law it is therefore hygienic. Circumcision was instituted solely as a religious rite long before the time of Moses, and was intended to mark distinctively "the peculiar people." Its adoption by other nations may very probably have been in the hope of securing the blessings that were poured so bountifully upon this people by Jehovah. Such mutilations were not uncommon among barbarous tribes, and, as this mark was the only visible sign of difference, superstition could have easily induced thousands to submit to its practice. In this manner the practice may have extended to widely remote people.

Whenever possible to "strip" the glans and secure a freely movable prepuce, it should be the operation chosen, since of two operations equally efficient the simpler one should be selected. In new-born children this method is nearly always feasible, and in a large proportion of all young children it will be found an easy one. As a rule, this separation is accomplished by the boy's own manipulations before he is eight years old; but it is better that it should be done by the physician in infancy.

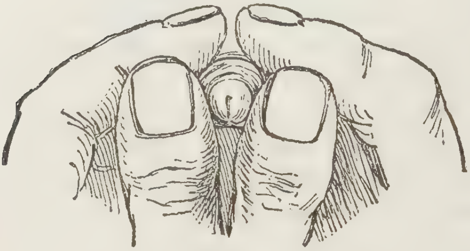
When contraction is slight, single or multiple incision of the mucous face is preferable to dilatation, although the latter may be practised if there is great fear of the knife. The inflammatory thickening following both incision, and dilatation to the point of rupture of mucous membrane, is undesirable if it can be avoided.

Finally, in all cases where reflex symptoms arise and where other plans fail to give the easily-sliding prepuce, circumcision should be performed. This operation as later described, and when practised *discriminatively*, is a most valuable agent.

The dangers of this plan are greater than those by the other methods, and deaths have resulted. Kohn alone saw six. In large boys and adults, when contraction has become established any operation short of circumcision is rarely useful, and these cases almost invariably require the removal of the entire mucous face of the prepuce.

Treatment.—1. *Stripping the Glans.*—The relief of simple adherent prepuce in a young infant requires no instrument. All that is necessary, after slight rigidity has taken place from manipulation, is to draw the foreskin slowly backward until the point of adhesion is reached. This exposure may sometimes require a full minute, or even more. Then the penis is to be grasped between the thumbs of the operator, while his fingers support the sides of the organ, when gentle backward rubbing or traction upon the margin of the rim will strip the prepuce from the glans as easily as the rind is peeled from the pulp of an orange. (Fig. 4.)

Fig. 4.



The same procedure (or, if preferred, two fingers may be placed upon each side of the organ) is applicable in the majority of cases of adhesion in older children, save that a probe or a grooved director is sometimes necessary to break up the union when it has become more decided. Only in older inflammatory cases will a dissection become necessary. The separation should be carried back until the sulcus behind the corona is fully exposed, when all smegma should be thoroughly wiped and scraped away and a small ring of borated or salicylated cotton dipped in cosmoline is made to encircle loosely the neck.

The removal of smegma is sometimes very difficult, as some of the particles of almost chalky or sandy hardness adhere with great tenacity. The flat end of a probe or an ear-scoop will best dislodge them.

The dressing should be at hand, since if the prepuce is allowed to remain long behind the corona, paraphimosis may result and great difficulty be experienced in reduction. A couple of probes or hair-pins will in such case assist greatly in compressing the glans and in bringing the foreskin forward. Of course it must never be allowed to remain retracted, lest sloughing result.

The foreskin should be slid back and forth several times, to see that it moves easily.

The cotton is allowed to remain *in situ* for several days, when it is removed, the parts thoroughly washed with one to ten-thousand sublimate solution, and the dressing applied as before.

After the tenth day the prepuce should be retracted daily by the mother of the child, and the parts washed clean, for reasons that have been explained on p. 640. This washing should be continued daily *for the remainder of life.*

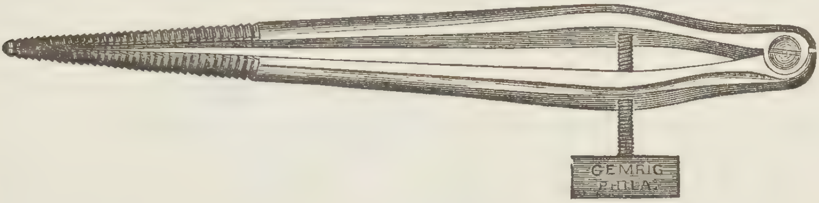
After a surgeon has practised this method a few times its simplicity and efficiency will so recommend it to his practice that he will circumcise only about half as many cases as formerly. Cases which at first seem to him intractable soon yield, and the glans is exposed.

Ether is rarely required, but cocaine is useful.

The rule should be always to secure a *freely movable prepuce;* and if the narrowing be such as to render retraction impossible, other means must be employed.

2. *Dilatation.*—This may be accomplished by an ordinary pair of dissecting- or of dressing-forceps, or by a uterine dilator, or, better, by one of the two-bladed or three-bladed dilating forceps[1] that have been designed especially for this purpose.

Fig. 5.



Levis's pattern, as shown in Fig. 5, depends upon screw-power for opening the jaws, and is very effective. Slow dilatation by tents or by forceps applied for twenty minutes twice daily will accomplish the purpose where time is not an element in the treatment[2] and where the knife is refused.

The disadvantage of forcible dilatation lies in the subsequent thickening and induration of the mucous membrane. This plan is largely practised, and is a valuable assistant to "stripping" in the more difficult grade of cases.

3. *Slitting.*—When the foreskin refuses to glide backward after adhesions are separated, slight incisions may be made to relieve the contraction that exists in the inner face of the prepuce. A probe-pointed straight bistoury is carried along a grooved director into the firmly-retracted opening, and with its back towards the glans several superficial nicks are made in the mucous surface of the prepuce. The guide for cutting will be to divide the most rigid parts until the hood slides freely over the glans.

Preliminary packing of the pouch with cotton saturated with cocaine solution will often obviate the necessity for ether, especially if the knife be concealed from the view of the child.

The dressing and subsequent treatment should be the same as in stripping.

Circumcision.—The method of performing circumcision will depend upon the amount of redundant skin. If long, it was formerly removed as in the Rabbinical manner,—*i.e.*, by drawing forward the prepuce, and severing it with one stroke of the knife, either with or without protection of the glans by a slit ivory or silver guard. The mucous face is then torn back and all the tissues pushed fully back of the corona. Hemorrhage, sloughing, and sometimes death have been the results of this practice. The arrest of hemorrhage by placing the penis in the wine-filled mouth of the Rabbi has been discontinued, as syphilis was thus easily communicated to the fresh surface. This dangerous practice has been abolished by the Paris Israelites, and, by the recent decree of the Commission of Surgeons acting in connection with the Grand Rabbi, many essential rules enforcing the strictest cleanliness of the Rabbis, infants, and instruments, have been adopted.[1] In hemorrhagic cases it has long been the custom after two deaths in a family to omit the operation. The repugnance to the mutilation is increasing to such an extent that certain Rabbis have ceased to insist upon it as a religious rite.

[1] Phila. Med. and Surg. Reporter, February 2, 1884, p. 137.

[2] Brit. Med. Jour., 1879, ii. 86; Trans. Ninth Internat. Med. Congress, 1887, vol. iii. pp. 459, 475.

Circumcision is performed by the surgeon in a variety of ways, and there have been devised many special forceps (Velpeau's, Skilling's, etc.),—some with fenestrated blades, some with peculiar clamps, others designed to permit the easy introduction of sutures, etc.,—but all of them are entirely unnecessary. Any forceps provided with parallel-closing blades so as to hold evenly the entire width of the foreskin is all that is needed. Figs. 6 and 7 are convenient forms.

FIG. 6.

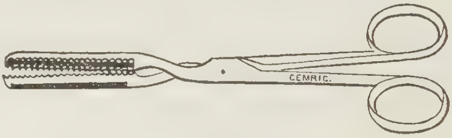

FIG. 7.

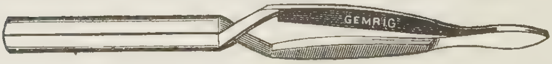


Ether is advisable, but, if there is any special objection to its use, partial local anæsthesia can be secured by ice, by ether spray, or by packing the foreskin both inside and out with cotton soaked in a four-per-cent. solution of cocaine for ten minutes and then inserting five or six hypodermic injections into the prepuce with the same solution, the effect being enhanced by the encircling of the penis at its base with a rubber band.

Not more than one-half to three-fourths of a grain of cocaine should be introduced beneath the skin, even in adults, lest poisoning follow. Deaths have resulted from a neglect of this rule. Cocaine is badly borne by the genito-urinary tract.[2]

Absolute cleanliness is imperative.

The prepuce is retracted so that its mucous surface can be seized, preferably with roughened forceps like Levis's (see Fig. 5), and drawn well forward. If tension is made upon the skin instead of on the mucous face as described, it may readily be drawn so far forward that even the integument over the corpora may be removed. The best plan is to sacrifice as little as possible of the integumentary surface, as it is all needed as a covering for the glans.

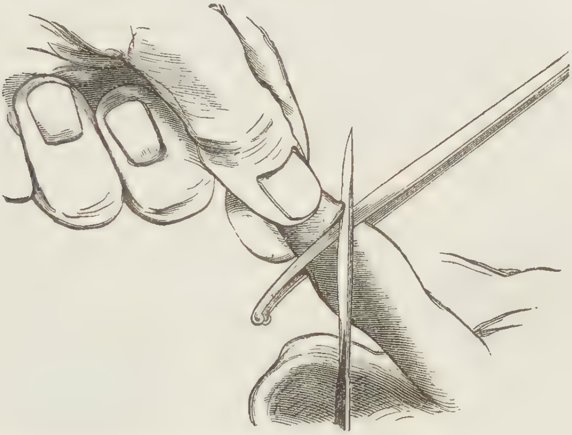
---

[1] Annales d'Hygiène, October, 1888; Jour. Amer. Med. Assoc., October 20, 1888, p. 576.

[2] University Medical Magazine, August, 1889, p. 638.

While the mucous surface is made tense *and the skin retracted*, the whole is firmly grasped by forceps *slanting forward* from the dorsum towards the frænum, so as to remove a smaller portion in the latter region (Fig. 8).

FIG. 8.



Prepuce embraced with the forceps preparatory to cutting off. (Agnew.)

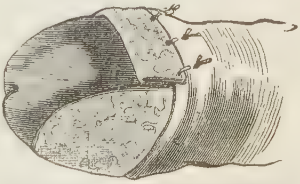
The section should be made in front of the forceps with a very sharp knife. The galvano-cautery has also been used.

Upon releasing the part, a portion of the mucous surface will still enclose the glans like a cap. This must be slit up and trimmed away nearly to the corona, so that the sulcus will be fully exposed.

After cleansing with one to five-thousand sublimate solution, and ligating with fine catgut any freely-bleeding points, lest the hemorrhage dissect up the loose tissue and interfere with union, the skin and mucous surfaces are united at five or six points by catgut or iron-dyed silk sutures (Fig. 9).

The gut stitches are preferable, as even so painless an operation as the removal of the threads is a terror to children and will make them unhappy for days. Silver wire or serresfines should never be used. The wound is again thoroughly disinfected and the part wrapped in gauze wet in one to ten-thousand sublimate solution. About the penis is then fashioned a nest of borated or salicylated cotton or wool, and a diaper applied as a retaining bandage, even in large children, so as to keep the penis upright. After each urination, if the dressings are soiled the parts should be thoroughly disinfected and the dressing applied as before. Union will be speedy and non-suppurative.

FIG. 9.



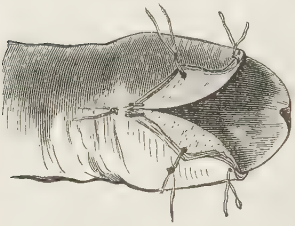
Mucous membrane slit up and one side reflected and stitched to the skin of the prepuce. (Agnew.)

Without the intervention of gauze the wool or cotton adheres too closely to the part. Close attention to minutiæ will save much pain and fright.

Another modification of circumcision in atrophic cases, where there is no great redundancy, is by *dorsal incision* of the prepuce. A probe or grooved director is first introduced, to sever adhesions and prevent the possibility of incising the urethra.

The section can be made by carrying a sharp bistoury along the director, puncturing the firmly-retracted skin at the corona, and dividing from before backward; or it can be made with scissors with one blunt point, like Taylor's.[1] The mucous surface is then thoroughly freed, the corners rounded off, and stitches applied as before (Fig. 10). The angles should never be left to form disfiguring flaps on each side of the penis. Liston made the section near the frænum, so as to retain the skin upon the glans, which is of advantage, and Jobert, Taylor, and others have operated similarly. Huc's plan of the *elastic ligature* and that of the écraseur are too tedious and painful, and should never be used except in hemorrhagic cases, and even then gradual dilatation is better.

FIG. 10.



Operation by incision. Skin and mucous membrane slit up and united by the interrupted sutures. (Agnew.)

In girls it is rarely found that any serious operation is necessary. The nymphæ are seldom so firmly adherent either to each other or to the labia majora that they cannot be separated by the exercise of a small amount of force. The hood of the clitoris can also be drawn back in the same manner by the fingers of the operator, and a dissection is rarely required. Temporary separation of the surfaces by borated cotton, and subsequent cleanliness after each urination, will be all the dressing that is required, but the surgeon should examine the case for several weeks, lest readhesion occur.

PARAPHIMOSIS.

Paraphimosis (παρά, "amiss," and φιμόω, "I bind") is a condition in which an abnormally narrowed prepuce becomes retracted behind the corona and remains there irreducible. It may also be produced by great swelling of the glans after injury, even when the foreskin is normal.

The condition is usually found in children as the result of their own or other lewd boys' action in forcing back the prepuce before it is thoroughly freed from the glans, or from placing strings, bands, etc., around it. In larger boys it frequently follows attempts at coitus. It has not unfrequently happened in the hands of physicians who have retracted the skin in balanitis to obtain a view of the glans.

The constriction at the neck of the penis speedily interferes with circulation, and both glans and prepuce become enormously swollen. The resulting inflammation may progress even to gangrene.

---

[1] Bumstead, Venereal Diseases, 5th ed.

Treatment.—A. *Manual Methods.*—The indications to be fulfilled in reduction are—(*a*) to reduce the size of the glans, (*b*) to draw forward the contracted prepuce, and (*c*) to reduce the consequent inflammation.

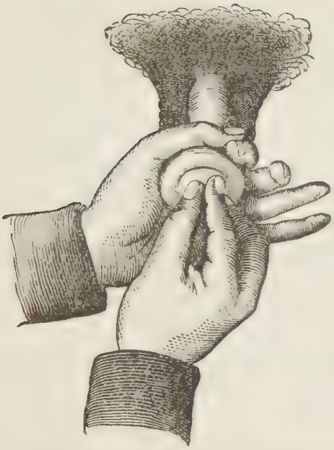
1. The lateral folds of skin may be grasped on each side by the surgeon with thumb and finger, the two thumbs thus acting as compressors of the glans while forward traction is made by thumb and finger on the contracted ring.

2. The engorged glans may be reduced by a spirally-applied band of rubber, which band, being continued up upon the body of the penis, may then be simultaneously unwound and withdrawn so as to slide the prepuce forward.

3. The glans is compressed by the thumb and fingers of one hand while the other hand draws forward the prepuce (Fig. 11), or the glans is compressed by the dorsums of both thumbs while four or more fingers are employed as tractors.

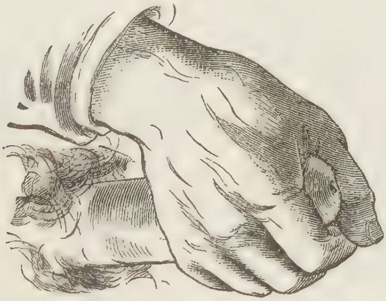
4. The glans is compressed by the firm grasp of the surgeon's hand for several minutes, after which the same hand is used to draw forward the foreskin (Fig. 12).

FIG. 11.



Phillips's method of reducing paraphimosis.

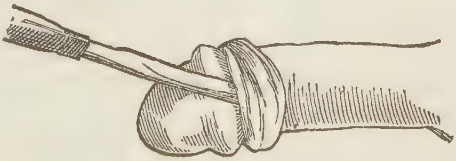
FIG. 12.



Agnew's method of reducing paraphimosis.

B. *Operative Measures.*—Should the surgeon fail to reduce the condition, or should the constriction have become indurated, it should be divided on the dorsum by slipping beneath it a blunt-pointed bistoury and relieving it freely (Fig. 13). The small hemorrhage will unload the vessels, and reduction will be easy.

FIG. 13.



The best subsequent dressing in all cases will be laudanum and ice-water, to which may be added any mild disinfectant, as boracic acid. Ice and cocaine freely applied will render all the manipulations much less painful, provided ether be not used. The pain is so great, however, that, unless it is desired to make an impression upon the mind of a lewd boy, anæsthesia should be employed.

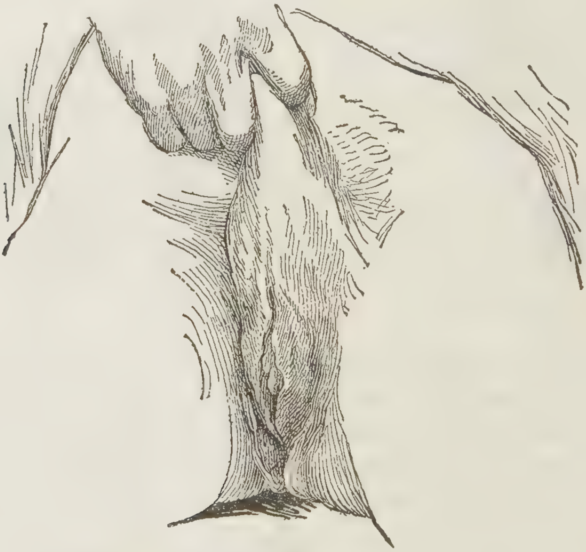
After the reduction of the inflammation, if the foreskin does not slide with perfect ease, circumcision should be performed.

HYPOSPADIA.

Hypospadia (ὑπό, "under," and σπάζω, "to open"), as named by Galen and subsequently minutely described by Dupuytren, is a deficiency of the urethra in which the outlet of the tube is present at some abnormal point between the extremity of the glans penis and the perineum.

Etiology and Pathogenesis.—This condition may be occasioned (1) by the absence of a portion of the lower wall of the urethra, (2) by a failure in coalescence of the lateral halves of the tube, or (3) by the rupture of the thin pouch which is usually known as a congenital dilatation of the urethra, thus creating what is really a congenital fistule. The arrest of development may be so slight as to show only the loss of the portion of the tube beneath the glans, constituting the *balanic* variety, or the opening may be *corporeal, scrotal,* or *perineal* (Fig. 14), names that are indicative of the point of exit.

Fig. 14.



The extent of deficiency will depend upon the degree of arrest in the development of the superior or inferior genital buds of Coste.

As the fusion of the lips of the genital groove arising from the urogenital sinus takes place from the perineum forward, it follows that the anterior portion is the point most frequently wanting. This fact of origin explains the persistent vulvar conformation in hypospadic males, since it indicates an arrest of development of the inferior genital buds at the time when differentiation takes place.[1]

Rarely will the mal-control of formation cease at the absence of the lower wall of the urethra alone, but deformities of penis, bladder, scrotum, and pubic bones will often coexist.

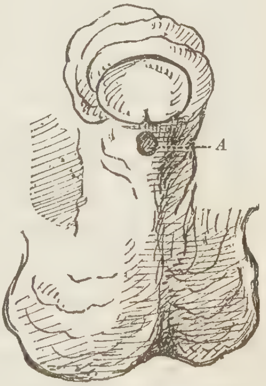
This vice of conformation is often hereditary. Woodman saw it in four generations, but only on the male side of the family, the male children of daughters being well formed.

Bouisson puts the frequency of hypospadia as once in every three hundred children born; but in my experience his estimate is too high.

The balanic variety, in which the opening exists beneath or just behind the glans, is the form most commonly found,[2] the imperfect track of the urethra being marked by a shallow sulcus along the under surface of the glans, in which groove I have once noted a small false pocket.

An opening at this point is rendered more serious, as regards copulation and fecundation, by the frequent occurrence of a coexistent short corpus spongiosum, and by dense bands near the abnormal opening that bend the head of the organ sharply downward over the orifice during erection (Fig. 15).

FIG. 15.



GLANS INCURVED BY SHORT CORPUS SPONGIOSUM.—*A*, meatus shown expanded.

A redundant preputial hood, partially adherent to the glans, often conceals the head of the penis. Sometimes there is a double meatus,[3] or the opening may exist at one side of the corona.[4]

In the corporeal variety the opening is usually larger, and the tube may exist in front of the orifice, the fistule possibly being due to a ruptured urethral pouch.

When the opening is scrotal or perineal, it is usually accompanied by cleft scrotum, and frequently by non-descent of the testes. The penis is often dwarfed, twisted, bifid, flattened, webbed, or even concealed in integumentary folds resembling labia.

When it is remembered that during the development from the genital buds there is at first no apparent difference in the two sexes, it will not seem strange that in the malformation of these parts great confusion may exist and the sex of the individual be very uncertain.[1] The further discussion of this subject will be found under Hermaphrodism, p. 669.

[4] London Lancet, 1884, ii. 773.

When the meatus is perineal, unless urination is performed in the position assumed by females the protection of the clothing is impossible.

Vesical irritation, eczema, and herpes præputialis are often troublesome. Sometimes the hypospadic opening forms a common opening for both urine and fæces.[2]

At death the majority of pseudo-females are found to have been hypospadic males.[3]

Diagnosis.—The discovery of the abnormal opening is rarely difficult, especially if the act of urination is watched.

The determination of the sex of a new-born babe with perineal hypospadia and other genital deformities will often be difficult, owing to the exceeding smallness of cavities and organs and the difficulties of exploration. The discussion of this problem is continued under Hermaphrodism, p. 669.

Prognosis.—The prospect of cure will depend not only upon the degree of the deformity, but also upon the patience, perseverance, and determination of the patient. When the orifice is at or near the glans and there is no incurvation during erection, the inconvenience is but slight and the future man will doubtless be fruitful. No operation is necessary, therefore, except for the sake of appearance. Fecundation is also possible when the opening is in the anterior part of the corporeal region. In the scrotal and perineal varieties ejaculation can take place only upon the vulva of the female, unless future mechanical skill shall construct a tube that can be used for elongating the urethra. If a penis of moderate size, however, be present, it is possible to construct a real urethra upon its under surface, even when the orifice is far back. Of course many failures will occur, and from two to six successive stages are often necessary, even in moderate cases. Every surgeon familiar with this class of operations knows, from repeated disappointments, that great patience is required even in simple cases. In children the diminutive character of the penis, the thinness of the raw edge of the skin-flaps, and the constant presence of urine, whether a catheter is used or not, make success always doubtful without frequent operations.

Treatment.—*Time for Operation.*—The general rules governing operation, as advised on p. 633, will apply in hypospadia. It is unwise to operate upon a young babe so long as there is no difficulty with urination, since the diseases of early infancy may readily cause death before serious mental or physical annoyance is experienced.

In order to facilitate the proper growth of the penis, the adherent preputial hood, if present, should be stripped from the glans very early in life, but the tissue of the redundant hood (Fig. 16) should not be sacrificed until the completion of operative measures, since it may be necessary to utilize it for plastic flaps.[1]

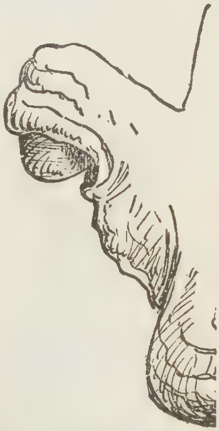
[3] Trans. Path. Soc. Lond., 1884, xxxvi. 309.

All surgeons who have had practical experience have learned that success is best attained by dividing the operative procedures into several stages.

FIG. 16.



Redundant prepuce partially concealing the glans.

1. *Straightening the Penis.*—This is accomplished by multiple open and subcutaneous incision of all restraining bands, whether they exist in the corpus spongiosum, in the cavernosa, or in the septum.

An encircling cylinder of adhesive plaster will assist in preventing retraction. When soiled, this should be washed with one to ten-thousand sublimate solution, or with boracic acid.

2. *Deepening the Groove.*—If the groove in the glans is too shallow to permit of the formation of a new urethra, or if the glans remains flexed, the furrow should be deepened by incising so freely into the substance of the glans that the resultant meatus will be on a straight line with the normal urethra. This incision may be median and single (Fig. 17), or multiple and branching (Fig. 18), the mucous membrane being undercut in order to prevent contraction during healing. This contraction is so exceedingly difficult to prevent that I now delay it until I am ready to proceed to the third stage of the operation.

FIG. 17.

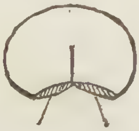


FIG. 18.

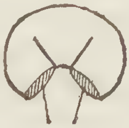

FIG. 19.

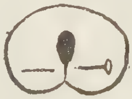


The old plan of tunnelling through the tissues with a hot wire has been nearly abandoned, although it is still occasionally attempted.[2]

It would be easier to produce such a pathway with the thermo-cautery, or with an instrument like a harness-maker's punch.

The bleeding from an incision, even when a considerable portion of glans-substance has been cut away, while free after the removal of the rubber tourniquet, is not dangerous, and can be controlled by pressure made upon an inserted catheter. If the groove is not deepened in this manner, failure will often occur in the formation of a new urethra by too great tension on the flaps. The sulcus is usually so shallow that many failures have occurred from the timidity of the operator.

---

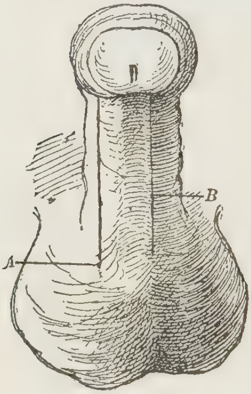
[1] Hardin, Manchester Medical Chronicle, 1889, x. 384.

[2] Australian Medical Journal, 1886, viii. 390.

Union is secured by fastening the lips over a section of a catheter by shotted wire sutures or by a pin (Fig. 19).

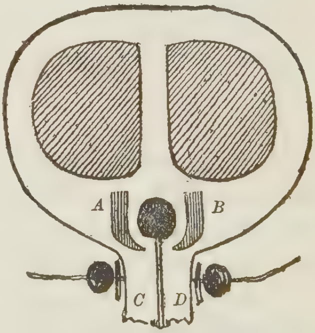
3. *Formation of a New Canal from the Extremity of the Glans to the False Opening.*—There are several methods of forming flaps for this purpose. An excellent one is the fashioning of one long and one short flap. The former is made by carrying an incision parallel to the course of the urethra as far outside the margin of the defective groove as the size of the penis will permit (Fig. 20, *A*). This flap is dissected inward towards the median line. A second incision, *B*, is now made just outside the line of the gutter on the opposite side, and a short flap is raised by dissection outward away from the median line. The long flap is then reverted over a catheter as a mould, the raw surface being left outward, and is tucked beneath the short flap, where it is secured by aseptic black silk or by catgut sutures.

Fig. 20.



Another plan, that of Duplay, is an exceedingly good one. With a catheter for a mould, two longitudinal incisions are made along the proposed line of the tube, at equal distances from the median line and about three millimetres from it, extending from the extremity of the glans to the anterior curve of the hypospadic opening. From these incisions short flaps are dissected inwardly, so that even after retraction they will still cover one-third or one-half of the catheter. Outwardly from these incisions the dissection is freely carried far enough to give an easy covering of skin for the catheter from the sides of the penis. When these parts are brought together, there will be four flaps, two short ones (Fig. 21, *A* and *B*), with bases looking towards the median line and with their epithelium-covered faces lying upon the catheter to form the bottom of the urethra. The two longer ones (*C* and *D*, Fig. 21), with bases attached near the inferior lateral portions of the penis and with raw surfaces inward, are superimposed and united to complete the new tube. A quilled suture is made by passing single wires through the edges of the long flaps and then shotting them over a perforated lead strip. Any further needed skin-approximation is made by shallow interrupted sutures.

Fig. 21.



Schematic plan of four flaps.

The catheter or a section of soft drainage-tube is allowed to remain in the anterior urethra for a few days, and the urine is passed as necessary through the false opening. The sutures should be removed on the fifth or sixth day, unless they occasion earlier irritation. When the sulcus in the glans has been deepened, this tube is a necessity to prevent contraction.

Another plan is to cut two wide longitudinal flaps with bases corresponding to the edges of the urethral gutter. Turning these with skin surfaces towards the urethra, their edges are united with fine, interrupted, thoroughly aseptic catgut sutures, the ends of which are left uncut.

To cover these raw surfaces flaps are taken from a redundant prepuce or scrotum, or the penis may be pushed through a slit made in the prepuce and the skin utilized as a flap. These superimposed flaps are to be sutured with their raw faces against the denuded surfaces of the first flaps by means of the free ends of the previous catgut stitches which have been left uncut for this purpose.

For cosmetic effect subsequent trimming will probably be necessary.

Preferably several months later, when all tendency to contraction of the urethra has certainly passed, the fourth step is to be made.

4. *Closure of the Hypospadic Opening.*—This will be accomplished by thoroughly paring the entire circumference of the gap and then drawing across it two flaps made as in any of the previous methods, and uniting them in the same way,—urethrorrhaphy or urethroplasty. At the option of the operator a catheter may be retained in the bladder and left open for three days, provided it does not produce irritation. After that time the urine may be passed naturally, care being taken to support the wound gently and to cleanse the line of incision thoroughly after each urination by a one to ten-thousand solution of corrosive sublimate.

Erections must be controlled by opium, bromides, camphor, or lupulin.

Subsequent contraction of the urethra must be overcome by progressive dilatation.

The chief cause of failure in union, aside from the necessary presence of urine, is found in the fact that young operators are timid about cutting long flaps, and thus too much tension is brought to bear upon the tissues.

The question as to the retention of a catheter in a plastic operation on the urethra is one that has puzzled all surgeons. The instrument is painful and annoying to the child, and not infrequently it produces cystitis. It does not accomplish the purpose for which it is designed, as the urine not only issues alongside of it but also follows back along its outer surface, and the wound is frequently drenched. It also becomes speedily encrusted or blocked. Until the final step of closing the abnormal opening is reached, I have, therefore, discarded it entirely. A section of catheter—or, better, a piece of soft drainage-tube, since it gives less pain in the movements of the child—is left in the anterior urethra for a few days, while urination is performed through the hypospadic opening, light pressure preventing the urine from passing forward. The sole use of the tube is to retain the patency of the canal. The parts are to be cleansed and rendered aseptic after each urination. Even when the final closure of the hypospadic orifice is undertaken, I have found that the catheter is often worse than useless in children, and that careful support of the wound during urination answers far better. Catheterization of a frightened child with a sore urethra is neither safe nor possible, even with cocaine, and it must always be remembered that this drug seems to have peculiarly serious effects when used in this region.

In severe cases with perineal opening and cleft scrotum, resembling hermaphrodism, a careful study of each case must be made, as plastic surgery may be able in a limited number of cases to secure such improvement of condition that subsequent marriage will be permissible.

When the penis is present, even though diminutive, it may be quite feasible to construct a urethra along its under surface. Mechanical art may sometimes provide a tube which can be inserted into the short urethra and act as a conductor of the semen to the os uteri in those cases where a hypospadic individual has been rash enough to contract marriage. In such a case also the plan of collecting the semen and injecting it into the cavity of the uterus by a syringe would be justifiable.[1]

If the child is careful to support the newly-constructed portion of the urethra by a judicious application of his fingers, he can do much, during the week following the removal of the stitches, to prevent a rupture of the delicate union.

CONGENITAL URETHRAL FISTULE.

In connection with hypospadia should be mentioned *congenital urethral fistule*, since it is a deformity occasioned by the same cause,—that is, a want of union at some portion of the lips of the urethral groove of the urogenital sinus. It may also be caused by a temporary or permanent closure of the anterior portion of the canal and the consequent rupture of an obstructive cyst.

Occasionally a congenital fistule permits the passage of both urine and fæces.[2]

A persistent Müllerian duct opening near the floor of the female urethra may resemble a fistule.[3] In these cases the retrograded Wolffian body is represented by cysts, the hydatid of Morgagni and the organ of Giraldes both being present.

Imperfect fusion of these Wolffian bodies produces many anomalies besides fistule, since errors of development or of union may occur at any point in their course as they extend downward from the rudimentary diaphragm in the fœtus to the exit from the pelvis.[4]

[3] Royal Med.-Chir. Soc. Lond., 1880, viii. 432; Brit. Med. Jour., September, 1879, 634; ibid., September 6, 1880; Lancet, 1879, iii. 654, 697, 727.

[4] Amer. Jour. Obstet., March, 1889, Nilsen; ibid., xiv. 94.

The Wolffian duct and Müller's ducts, lying in their respective order along the external border of the Wolffian bodies, are also liable to deformation, especially the Müller's ducts, as from their proper fusion are formed the uterus and the vagina.

Treatment.—When the fistule is small, it is sometimes sufficient to cauterize its edges and then to stimulate healing by applications of tincture of iodine, while the urine is constantly drawn by a catheter. At other times the freshening of the edges of the opening and sealing with collodion and gauze are sufficient to effect a closure. The thermo-cautery may also be used as a freshening agent, but the knife is usually, as in all other fistules, the best of "caustics." Should these means fail, a plastic operation should be performed as in hypospadia by urethrorrhaphy or urethroplasty. (Figs. 22, 23, 24.)

SHORT FRÆNUM OR SHORT CORPUS SPONGIOSUM OR INCURVED PENIS.

This deformity rarely, if ever, exists without hypospadia, and it has already been considered on pp. 649. For its relief every retaining band should be divided, either by open incision or subcutaneously.

EPISPADIA.

Epispadia (ἐπί, "upon" or "above," and σπάζω, "I open") is the absence of the upper urethral wall throughout some portion of its extent, accompanied by a greater or less degree of separation of the corpora cavernosa.

Etiology and Pathology.—This vice of conformation is possible from intra-uterine traumatism of governing cells, or from hereditary taint.[1] There follows an arrest of development, or a failure of union, or an uneven advancement in the evolution of the external and internal genital nodules. The existence of the urethra upon the dorsal portion of the penis is due to non-union and falling apart of the corpora cavernosa, which permit the advancement of the urethra during the tardy development of the internal genital nodules.

In the fifth or sixth week of intra-uterine life the cloaca or common cavity divides into the uro-genital portion in front and the anal in the rear. By the end of the second month the genital tubercle from which springs the penis, scrotum, etc., is formed. Should this genital tubercle be misdirected or misguided by the abnormal closing or bridging of the septum, the penis may be placed behind instead of in front of the uro-genital canal.

In other cases there may be an arrest of development, so that the two fasciculi destined to form the spongy portion of the urethra fail to unite, thus leaving the urethra open above. Should the superior external genital buds of Coste unite below instead of above in the corpora cavernosa, the groove will be superposed instead of subjacent. Should this unite as far forward as the glans, there will exist a dorsal tube; but if union fails to occur, then epispadia results. Unequal advancement of the internal and external nodules will give a similar result. The studies of Freund, Kölliker, and Kobalt are valuable in this subject.[2]

Complications.—Fissure of the pubes, exstrophy of the bladder, clubbed, distorted, and twisted penis, cryptorchidism, hernia, and other malformations frequently coexist.[3] Billroth saw two cases of double clitoris in which, with the epispadia, prolapsus vesicæ existed.[4] This prolapse of bladder is common in males, and more or less incontinence of urine is always present.

The meatus is rarely found well forward upon the dorsum of the penis, but Anderson,[5] in twenty epispadic cases, male and female, found the urethral opening to be two and a half inches below the upper border of the symphysis. The prepuce is often irregular and redundant. The broad flattened penis applied against the abdominal wall sometimes acts as a valve and assists in retaining the urine[6] in the exstrophic bladder. (Fig. 25.)

In urination much annoyance is experienced by the scattering of the stream. In the female, fissure of the pubic bones is common, with a large opening directly into the bladder.[7]
